**Figure 73-2** Two models are shown for the pathogenesis of salivary gland inflammation in Sjögren's syndrome. **A,** Glandular hypofunction is explained by tissue loss secondary to immune attack, resulting in cytotoxic cell death and apoptosis. Epithelial cells likely play a central role in this process by several mechanisms: antigen-presentation and T cell activation; production of pro-inflammatory cytokines, such as IL-1, IL-6, TNF, IL-12, and IL-23; and secretion of proteases. Epithelial cells also upregulate expression of Fas (FAS) and Fas ligand (FASL), cell surface molecules involved in the activation of apoptotic pathways. Other immune cells such as T cells, B cells, macrophages, and dendritic cells serve to amplify the chronic inflammatory response. In model **B,** glandular hypofunction results from downregulation of receptor-mediated secretion of salivary fluid into the ductal lumen. Acetylcholine binds to muscarinic type 3 receptor (M3R) on the surface of acinar cells, stimulating production of the second messenger inositol 1,4,5-triphosphate ($IP_3$). $IP_3$ in turn diffuses through the cytoplasm until it binds its receptor, $IP_3R$, on the endoplasmic reticulum. This interaction causes calcium to be released into the cytoplasm, which opens $Ca^{2+}$-sensitive chloride channels on the apical membrane of the cell. Electrochemical neutrality is preserved when $Na^+$ follows chloride across the membrane, while the osmotic gradient propels the water into the ductal lumen. Mechanisms of immune-mediated glandular hypofunction might include inhibition of acetylcholine release by cytokines, increased breakdown of acetylcholine in the epilemmal space by upregulated production of cholinesterases, blockade of M3R by autoantibodies, inhibition of intra-cellular signaling pathways involved in the fluid secretory process, or altered expression of aquaporin 5 (AQP5), which appears to be primarily responsible for water movement through the apical cell membrane. See reference 96 for more details. BAFF, B cell activating factor; ICAM-1, intercellular adhesion molecule-1; MHC, major histocompatibility complex; MMP-9, matrix metalloproteinase-9; PLC, phospholipase C.

**TABLE 73-3** Differential Diagnosis of Primary Sjögren's Syndrome

| Condition | Associated Clinical/Radiologic/Pathophysiologic Features | Immunologic/Histopathologic Profile |
|---|---|---|
| **Dry Eye (Keratoconjunctivitis Sicca)** | | |
| ***Aqueous Tear Deficiency (Failure of Lacrimal Tear Secretion)*** | | |
| Sarcoidosis* | Lacrimal and parotid gland enlargement, cervical and hilar adenopathy, ILD, uveitis, arthralgia/arthritis, erythema nodosum | ANA negative or low titer; noncaseating granulomas in multiple organs (e.g., lymph nodes, lungs, spleen, liver, skin, salivary glands) |
| Chronic hepatitis C infection | Chronic hepatitis | Serum hepatitis C virus antibodies; hepatitis C viremia |
| Chronic GVHD | Occurs after allogeneic hematopoietic stem cell transplantation; other ocular features include sterile conjunctival inflammation and scarring, with progressive loss of goblet cells and dysfunction of meibomian glands | Lacrimal gland fibrosis, with mild chronic inflammation |
| Sensory block | Corneal surgery (LASIK), contact lens wear, diabetes | |
| Motor block | Cranial nerve VII damage | |
| Age-related | None | |
| Systemic drugs† | | |
| ***Evaporative (Excessive Water Loss from the Ocular Surface)*** | | |
| Meibomian gland deficiency | Ocular redness and burning; increased tear break-up time and tear hyperosmolarity; secondary to posterior blepharitis, acne rosacea, seborrheic dermatitis, and drugs (e.g., retinoids) | |
| Cicatricial pemphigoid‡ | Scarring of the meibomian orifices, loss of goblet cells | |
| Poor lid congruity or low blink rate | Proptosis (poor lid congruity), Parkinson's disease (low blink rate) | |
| Vitamin A deficiency | Impaired goblet cell development | |
| **Dry Mouth (Hyposalivation)** | | |
| Amyloidosis | Nephrotic syndrome | ANA negative; monoclonal gammopathy; biopsy often shows amyloid deposits |
| Hemachromatosis | Cirrhosis | Labial salivary gland biopsy with heavy hemosiderin deposits in the ductal epithelium and loss of acinar glands |
| Chronic GVHD | Salivary gland dysfunction less common than lacrimal gland dysfunction; may be associated with oral mucosal involvement of chronic GVHD | Periductal inflammation, fibrosis, and glandular atrophy |
| Chronic hepatitis C infection | See previous text | Labial salivary gland biopsy shows chronic inflammation similar to that of Sjögren's syndrome |
| Diabetes mellitus | Type I or type II diabetes | |
| Radiation therapy | Side effects after radiotherapy for head and neck cancer | Lack of functional acinar cells; damage to ducts, blood vessels, and nerves |
| Anxiety | | |
| Systemic drugs† | | |
| **Parotid Gland Enlargement** | | |
| Sarcoidosis* | See previous text | See previous text |
| IgG4-related diseases | Multiorgan involvement: lacrimal and salivary gland enlargement, chronic sclerosing sialadenitis, autoimmune pancreatitis, sclerosing cholangitis, lung nodules, interstitial pneumonitis, aortitis, interstitial nephritis, prostatitis, orbital pseudotumor, dacroadenitis, meningitis, hypophysitis | High serum IgG4 levels; lymphoplasmacytic infiltrate and abundance of $IgG4^+$ plasma cells in tissues |
| Multicentric Castleman's disease | Lacrimal and salivary gland enlargement (uncommon); fever, lymphadenopathy, hepatomegaly, edema, and ascites (common); increased incidence of non-Hodgkin's lymphoma | Elevated serum IL-6 levels; some patients with increased serum IgG4 levels; lymph node biopsy shows interfollicular plasmacytosis |
| Diabetes mellitus | More common in type II than type I diabetes | Sialadenosis |
| Alcoholism | | Sialadenosis |
| HIV lymphoepithelial lesion | Bilateral involvement | Extensive lymphoid infiltrate with reactive germinal centers ($CD8 > CD4^+$ T cells) |
| Benign tumors | Painless swelling of the parotid gland; usually unilateral but sometimes bilateral | Pleomorphic adenoma (usually unifocal); Warthin tumor: often multifocal and bilateral; oncocytoma; many other types |

**TABLE 73-3** Differential Diagnosis of Primary Sjögren's Syndrome—cont'd

| Condition | Associated Clinical/Radiologic/Pathophysiologic Features | Immunologic/Histopathologic Profile |
|---|---|---|
| Malignant carcinoma | Painless swelling of the parotid gland, facial nerve palsy | Most common: mucoepidermoid carcinoma, acinic cell carcinoma, adenoid cystic |
| Primary B cell lymphoma | Unilateral or bilateral parotid gland swelling | Marginal zone B cell lymphoma most common subtype (also called *MALT-type*); follicle center and mantle zone lymphomas may also occur in this region; diffuse large B cell lymphoma (rare) |
| Primary T cell lymphoma | Rarely may present as a parotid gland mass; HTLV-1-associated | Anaplastic large cell or diffuse pleomorphic (medium and large cell) |
| Calculous duct obstruction | Painful enlargement of salivary glands | Ruptured ducts and obstructive granulomas |

*May coexist with primary Sjögren's syndrome.
†Common offending drugs include: anticholinergics (e.g., antihistamines, tricyclic anti-depressants, antispasmodics), clonidine, diuretics, isotretinoin, estrogen replacement therapy, amiodarone.
‡May also destroy the lacrimal gland and cause lacrimal duct obstruction late in the clinical course.
ANA, Anti-nuclear antibodies; GVHD, graft-versus-host disease; HIV, human immunodeficiency virus; HTLV-1, human T lymphotropic virus type 1; IL-6, interleukin-6; ILD, interstitial lung disease; MALT, mucosa-associated lymphoid tissue.

Two complications of xerostomia are important to the care of patients, especially those with severe deficits in salivary flow. One complication is rampant dental caries, cracked teeth, and loose fillings. Oral candidiasis, the other frequent complication, typically manifests as the atrophic variant, which is characterized by erythema and atrophy of the oral mucosa and filiform papillae on the dorsum of the tongue, with angular cheilitis. Sometimes, a thin, white exudate may appear on the surface of the tongue. The "thrushlike" variant of oral candidiasis is seen much less frequently in patients with xerostomia except in the face of recent antibiotic therapy.

Approximately one-quarter of patients with primary Sjögren's syndrome suffer enlargement of the parotid or submandibular glands during the course of their disease. Chronic swelling is usually painless and may be unilateral or bilateral; it is often diffuse and firm by palpation. Transiently painful episodes of acute swelling and tenderness may also punctuate the clinical course. Acute swelling of the major salivary glands results mostly from dried mucus transiently obstructing the major ducts; it usually subsides within a few days with conservative therapy. Rarely, bacterial infections may cause acute salivary gland swelling and should be considered as a possible etiology if the patient has a fever or other constitutional complaints. Asymmetric gland enlargement with palpable hard nodules that are increasing in size may indicate a neoplasm such as a lymphoma.

## Involvement of Other Exocrine Glands

Glandular hypofunction may affect the nasal passages (meatal obstruction from dried mucus), larynx (hoarseness), trachea (cough), vagina (dyspareunia), and skin (pruritus), producing symptoms of dryness. Virtually any exocrine gland may be involved in this disease.

## Extraglandular Manifestations

Nearly three-quarters of patients with primary Sjögren's syndrome manifest signs or symptoms of extraglandular disease. Extraglandular involvement is more likely to occur in patients with serum anti-Ro/SS-A and anti-La/SS-B antibodies, as well as hypergammaglobulinemia, cryoglobulinemia, and hypocomplementemia.[104] However, only approximately 25% of patients with primary Sjögren's syndrome develop moderate or severe extraglandular disease.

### Fatigue

Fatigue, a complex and multifaceted phenomenon, occurs in approximately 70% of patients with primary Sjögren's syndrome.[105] It is also a symptom of depression, chronic anxiety, fibromyalgia, and sleep deficit, as well as a side effect of certain medications. The United Kingdom Sjögren's Interest Group has developed an instrument called the Profile of Fatigue and Discomfort–Sicca Symptoms Inventory (PROFAD-SSI) to specifically measure both somatic (needing rest, poor starting, low stamina, weak muscles) and mental fatigue (poor concentration, poor memory) in this disease.[106] In 547 patients with a confirmed diagnosis of primary Sjögren's syndrome, somatic fatigue was the dominant predictor of physical function and general health.[107] The relative contribution of behavioral and cognitive variables to fatigue was studied in 94 patients with primary Sjögren's syndrome.[108] Fatigue was prominent among patients in this study without depression, and it was only partially explained by psychosocial variables. The link between fatigue and "biologic disease activity" is not fully understood in primary Sjögren's syndrome. Increased serum cytokines such as IL-6 and type I IFNs, as well as neuroendocrine and autonomic dysfunction, are postulated to be contributing factors to the physical and mental aspects of fatigue in this setting.[105]

### Raynaud's syndrome

Raynaud's syndrome has been reported in 13% to 33% of patients with primary Sjögren's syndrome, and often precedes the onset of sicca symptoms by several years.[109] Digital ulcers occur only rarely.

### Skin

Among the dermatologic manifestations, the most common are xerosis, or dry skin, eyelid dermatitis, and angular

cheilitis. In addition, many patients develop a variety of other cutaneous manifestations, including annular erythema, purpura, and urticarial vasculitis. Annular erythema has been described in several forms: a donut-ring–like erythema with an elevated border (type I); a subacute cutaneous lupus erythematosus (SCLE)-like lesion with marginally scaled polycyclic erythema (type II); and a papular insect bite–like erythema (type III).[110] Histopathologically, these lesions are characterized by a deep perivascular lymphocytic infiltrate without the epidermal changes associated with lupus.[111] In some cases, immunoglobulin and complement deposition is observed along the basement membrane with liquefaction degeneration in the basal layer of the involved skin. The type I lesion appears to be specific for primary Sjögren's syndrome, occurring predominantly in Asian as opposed to Western populations.

Cutaneous vasculitis may be expressed in several different forms, including palpable purpura, erythematous papules or macules, and ulcers, with lesions predominantly located in the lower limbs.[112] Such lesions are frequently accompanied by other extraglandular manifestations of disease, such as arthritis, peripheral neuropathy, Raynaud's syndrome, anemia, elevated erythrocyte sedimentation rate, hypergammaglobulinemia, serum rheumatoid factor, and serum anti-Ro/SS-A and anti-La/SS-B antibodies. In one study, among the 52 cases of cutaneous vasculitis, 27% and 50% occurred in patients with and without cryoglobulinemia, respectively; 21% of cases were classified as *urticarial vasculitis*.[112] Livedo reticularis has also been described in this setting.

### Joints

Polyarthralgia occurs frequently in patients with primary Sjögren's syndrome. In a retrospective study, articular symptoms in primary Sjögren's syndrome had a prevalence rate of 45%.[113] Although most patients complain only of polyarthralgia, a subset may experience objective signs of synovitis, which is nonerosive, symmetric, and polyarticular of waxing and waning intensity. Joint symptoms may precede the diagnosis of primary Sjögren's syndrome in as many as one-third of cases.[114] In two separate studies, anti-citrullinated protein antibodies (ACPA) were detected in serum from 7.5% and 9.9% of patients with primary Sjögren's syndrome.[115,116] However, in only one of these studies was their presence closely associated with synovitis,[116] and in neither study did it appear that serum ACPA positivity was associated with radiographic erosions or progression to rheumatoid arthritis.

### Lung

Involvement of the airways and lung parenchyma in primary Sjögren's syndrome may take several forms, including xerotrachea and xerobronchitis; nonspecific interstitial pneumonitis (NSIP); lymphocytic interstitial pneumonitis (LIP), now considered a subset of NSIP; usual interstitial pneumonitis (UIP); bronchiolitis; and lymphoma.[117] The estimated prevalence of pulmonary involvement in primary Sjögren's syndrome varies depending on the thoroughness of the evaluation. In one study of 123 patients with primary Sjögren's syndrome, 11.4% showed pulmonary signs or symptoms and/or impaired pulmonary function with abnormal chest computed tomography (CT) findings at the time of evaluation.[118]

Evidence of small airways dysfunction is found often in asymptomatic patients with normal radiologic studies. In symptomatic patients, NSIP appears to be the predominant type of lung involvement. The diagnosis can often be made on the basis of clinical presentation, pulmonary function tests (PFTs), and abnormal chest CT findings. PFTs in patients with NSIP show a restrictive pattern with reduced diffusion capacity of lung carbon monoxide (DLCO). Chest CT scans reveal ground-glass opacities and a reticular nodular pattern. Bronchoalveolar lavage (BAL), which is not usually required for diagnosis, shows evidence of alveolar inflammation, with elevated neutrophil or lymphocyte counts, or both. LIP, a subset of NSIP, is also associated with a restrictive pattern on PFTs. Chest CT findings are ground-glass opacities and thin-walled cysts, with centrilobular nodules, interlobular septal thickening, and bronchovascular bundle thickening (Figure 73-3A). Microscopically, the lung biopsy from patients with LIP shows a diffuse interstitial infiltrate composed of lymphocytes, plasma cells, and histiocytes that expand the interlobular and alveolar spaces (see Figure 73-3). The PFTs in patients with UIP also show a restrictive pattern such as NSIP and LIP, but lower lobe fibrosis, honeycombing, and traction bronchiectasis seen on chest CT distinguish it from these other two types. Follicular bronchiolitis is characterized histopathologically by nodular lymphocytic infiltrates with GC-like structures encircling respiratory bronchioles. In patients with bronchiolitis, PFTs may show a restrictive or obstructive functional defect. The chest CT scan usually displays reticulonodular infiltrates, but it may be healthy in mild cases.

Lung biopsy can reveal evidence of NSIP, bronchiolitis, or other pathologic processes. Ito and colleagues[119] evaluated 33 patients with primary Sjögren's syndrome that had biopsy-proven lung disease and found evidence of NSIP in 20 (61%), non-Hodgkin's lymphoma in four (12%), diffuse bronchiolitis in 4 (12%), and amyloid in 2 (6%). PFTs demonstrated restrictive changes in 19 (58%) patients and obstructive changes in 3 (9%) patients. Analysis of BAL fluid from all of the 28 patients who had this procedure was uniformly abnormal, showing elevated lymphocyte counts in 18 (64%) and elevated neutrophil counts in 19 (68%). In 31 patients, chest CT findings revealed an NSIP pattern in 14 (45%) and a UIP pattern in 4 (13%); 3 patients (10%) showed a pattern of organizing pneumonia. There were no cases of LIP in this series. By comparison, Parambil and colleagues[120] evaluated 18 patients with biopsy-proven lung disease and found a histopathologic pattern of NSIP in 5 (28%) patients, organizing pneumonia in 4 (22%) patients, UIP in 3 (17%) patients, LIP in 3 (17%) patients, lymphoma in 2 (11%) patients, and amyloid in 1 (6%) patient. Pulmonary arterial hypertension is a rare complication of Sjögren's syndrome.[121]

### Kidney

Renal disease of clinical significance in primary Sjögren's syndrome is present only in approximately 5% of patients and includes tubular interstitial nephritis, type I renal

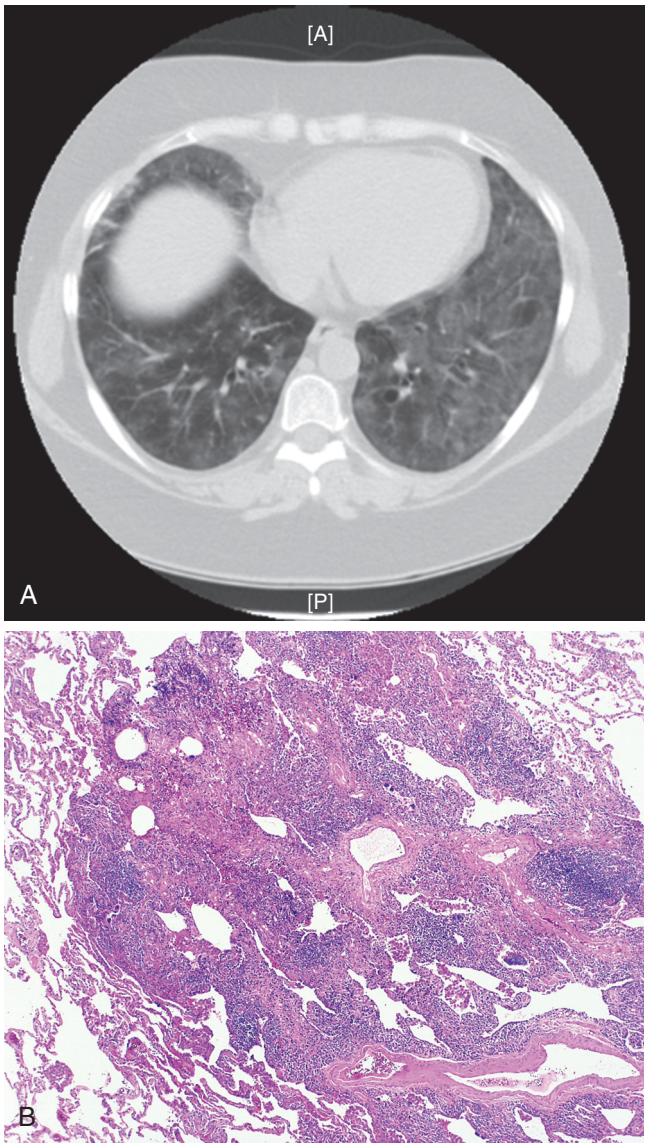

**Figure 73-3** Lymphocytic interstitial pneumonitis (LIP) in a 44-year-old woman with primary Sjögren's syndrome. **A,** A slice through the lower lobes of a chest computed tomography scan shows diffuse ground-glass opacities, a scattering of multiple nodules in the periphery, and many thin-walled parenchymal cysts. **B,** Histopathologic examination from a wedge resection of the lower lobe of this patient shows a patchy, nodular interstitial infiltrate composed of mononuclear cells, with widening of the interlobular and alveolar spaces, consistent with LIP.

tubular acidosis (RTA), glomerulonephritis, and nephrogenic diabetes insipidus. Tubular interstitial nephritis, which is characterized histopathologically by a peritubular lymphocytic infiltrate and fibrosis, rarely progresses to end-stage renal disease (see Figure 73-3A).[122,123] A patient with primary Sjögren's syndrome has been described with tubular interstitial nephritis and acquired Gitelman's syndrome, with absence of a sodium chloride co-transporter in the distal convoluted tubules.[124] Rarely, severe potassium wasting from type I RTA can lead to muscle paralysis.[125] Glomerular disease occurs less commonly in this setting and may take several forms, including membranous, membranoproliferative, mesangial proliferative, and focal crescentic glomerulonephritis. Glomerular disease is most often the result of immune complex deposition in the kidney and is more frequently associated with lymphoma than tubulointerstitial disease.[126]

### Gastrointestinal

Patients with primary Sjögren's syndrome have an increased frequency of gastrointestinal symptoms compared with the general population. Dysphagia and heartburn are particularly common complaints that may result from impaired salivary flow or esophageal motility, or both. Approximately one-third of patients with primary Sjögren's syndrome have varying degrees of esophageal dysfunction, although many studies have been unable to correlate symptoms of dysphagia with a functional abnormality.[127] The results of one study suggest that patients with primary Sjögren's syndrome do not have a primary disturbance of esophageal motility, but rather defective clearance of esophageal acid that exposes the esophageal lining to acid in excessive amounts, which in turn, produces morphologic changes and secondary dysmotility.[128] Other results suggest parasympathetic dysfunction might be at the root of the esophageal abnormalities.[127] A case has also been described of a patient with primary Sjögren's syndrome in whom esophageal achalasia developed in the setting of a sensory ataxic neuropathy, which damaged the myenteric plexus and produced the esophageal abnormality.[129] In addition, chronic atrophic gastritis, which may cause dyspeptic symptoms, has been reported in a small number of cases of primary Sjögren's syndrome.[130]

Liver enzyme abnormalities may develop in patients with primary Sjögren's syndrome for a variety of reasons, most often from an associated disorder such as hepatitis C virus infection, autoimmune hepatitis, primary biliary cirrhosis, or a nonspecific hepatitis.[131] Bowel symptoms such as abdominal pain and constipation occur more commonly in patients with primary Sjögren's syndrome than healthy controls, but their etiology is often obscure.[132]

### Nervous System

Neurologic abnormalities are protean in primary Sjögren's syndrome, with varied patterns of peripheral and central nervous system (CNS) involvement. The prevalence of central nervous system involvement that can be directly attributed to primary Sjögren's syndrome is likely to be in the range of 1% to 2%, but much higher rates have been reported with more liberal case definitions. For example, higher prevalence rates are noted when mood disturbances and minor cognitive and affective disturbances are included in the definition of CNS involvement. Neuropsychiatric symptoms such as depression and minor cognitive disturbances occur in approximately one-third of patients with primary Sjögren's syndrome. However, these neuropsychiatric problems are clinical disorders that occur frequently in the general population and in patients with chronic diseases in general. Rarely, cases have been described in which severe cognitive dysfunction develops in patients with primary Sjögren's syndrome. Brain MRI scans in these instances typically show nonspecific T2-weighted, high-intensity signals in the white matter that have an uncertain relationship to the clinical CNS findings. Focal CNS

deficits have also been rarely described in patients with primary Sjögren's syndrome, and include optic neuropathy, hemiparesis, movement disorders, cerebellar syndromes, recurrent transient ischemic attacks, and motor neuron syndrome.[133] In addition, spinal cord syndromes resembling multiple sclerosis such as transverse myelitis and progressive myelopathy have also been reported in patients with primary Sjögren's syndrome.[134] Patients with primary Sjögren's have been described, too, with neuromyelitis optica in association with serum anti–aquaporin-4 antibodies.[135]

Peripheral nervous system involvement is among the most common of the extraglandular features of primary Sjögren's syndrome. In a cross-sectional study, peripheral neuropathy was diagnosed in 17 (27%) of 62 patients with primary Sjögren's syndrome on the basis of a conventional neurologic examination.[136] However, only 34 (55%) in this group had abnormal nerve conduction velocity studies, including 19 (31%) with a motor neuropathy, 8 (13%) with a sensory neuropathy, and 7 (11%) with a sensorimotor neuropathy. Some of the others with normal nerve conduction velocity studies may have had a small fiber neuropathy. Other peripheral neuropathies that have been reported in patients with primary Sjögren's syndrome are cranial neuropathies, autonomic neuropathies, and multiple mononeuropathies.[133] Most cases of peripheral neuropathy are dominated by sensory symptoms and typically do not progress to cause motor weakness.

### Vasculitis

Beyond lower extremity purpura, systemic vasculitis appears to be a rare manifestation of primary Sjögren's syndrome. A small vessel vasculitis and cryoglobulinemia may develop in patients in the absence of hepatitis C virus infection. A medium-sized vessel vasculitis may rarely occur with features ranging from mononeuritis multiplex to ischemic bowel.

### Risk for Cardiovascular Disease

Patients with primary Sjögren's syndrome have increased risk for cardiovascular disease based on a twofold increase in prevalence of hypertension and hypertriglyceridemia compared with healthy matched controls.[137] The impact of these risk factors on cardiovascular outcomes in patients with primary Sjögren's syndrome is unknown.

## Lymphoma

Non-Hodgkin's lymphoma (NHL) is a complication of primary Sjögren's syndrome with important prognostic significance. In a European study, the prevalence of NHL was determined to be 4.3%, with a median time of approximately 7.5 years from the diagnosis of primary Sjögren's syndrome to the development of NHL.[138] Several histopathologic types of NHL have been described in association with primary Sjögren's syndrome, including marginal zone B cell lymphoma, follicular cell lymphoma, diffuse large B cell lymphoma, and lymphoplasmacytoid lymphoma. Marginal zone B cell lymphoma, which is a family of low-grade B cell lymphomas, is by far the predominant type of NHL associated with this chronic autoimmune disease.

The mucosa-associated lymphoid tissue (MALT) lymphoma, a marginal zone B cell lymphoma, is the most common type to occur in primary Sjögren's syndrome (Figure 73-4A). It develops at extranodal sites in relation

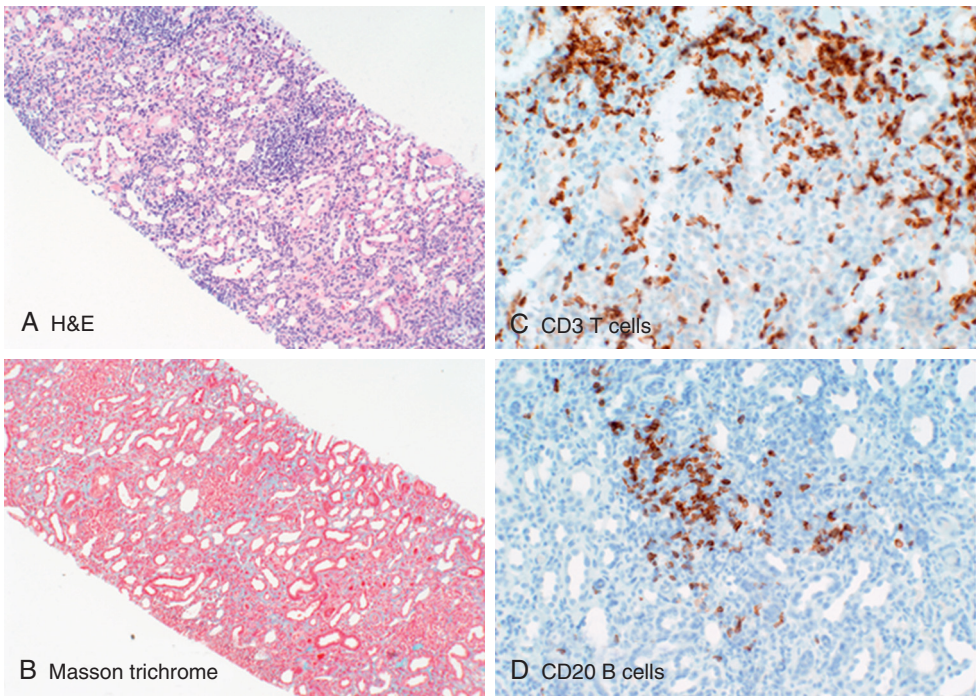

**Figure 73-4** Histopathology of a 57-year-old woman with chronic tubulointerstitial nephritis, consistent with renal involvement in primary Sjögren's syndrome. **A,** Hematoxylin-eosin (H&E) staining. **B,** Masson trichrome staining. **C,** Anti-CD3 staining of T cells. **D,** Anti-CD20 staining of B cells. Dense lymphoplastic infiltrate in the interstitium, with fibrosis and tubular atrophy (**A** and **B**). The majority of the mononuclear cells are T cells **(C),** with fewer numbers of B cells often in small aggregates **(D).**

to mucosal or glandular epithelium, such as the lacrimal and salivary glands, lung, gastrointestinal tract, and skin. The earliest histopathologic feature of MALT lymphoma is the finding of monocytoid B cells surrounding the epithelium. Immunochemical staining of these lesions shows their clonality in revealing monotypic infiltrates of either Igκ- or Igλ-light chains.[138] With progression, these lesions show increasing proliferation of neoplastic cells, replacement of reactive follicles, and ductal dilatation. In primary Sjögren's syndrome, MALT lymphomas most often develop in the salivary glands, but they may also develop at other extranodal sites, especially the lung and gastrointestinal tract. In primary Sjögren's syndrome, a fivefold increased risk for lymphoma is conferred by the presence of parotid gland enlargement, splenomegaly, lymphadenopathy, neutropenia, cryoglobulinemia, or low C4.[139]

### Associated Diseases

Primary Sjögren's syndrome has been associated with a higher risk for other autoimmune diseases, including thyroid disease, autoimmune hepatitis, primary biliary cirrhosis, and celiac disease. A recent large study found an increased frequency of autoimmune thyroid disease among patients with primary Sjögren's syndrome (6.2%) compared with the rate in the general population of 1% to 2%. However, because of varied definitions of thyroid disease this association has been inconsistent across studies.[140,141] Autoimmune hepatitis and primary biliary cirrhosis occur in less than 5% of patients with primary Sjögren's syndrome; more precise estimates of their prevalence are not available because of the absence of well-controlled studies. A Hungarian study showed a 10-fold higher rate of celiac disease in patients with primary Sjögren's syndrome compared with healthy controls.[142]

## DIAGNOSIS AND DIAGNOSTIC TESTS

### Keratoconjunctivitis Sicca and Xerostomia

A diagnostic suspicion of Sjögren's syndrome is initially raised by complaints of dry eyes and dry mouth. However, many patients may not volunteer this information because they do not feel it is important enough to bring to the attention of the physician. Therefore it is essential for the physician to inquire about these symptoms if the patient does not mention them during the initial history taking. In patients with symptoms of dry eyes and dry mouth, the next step is to confirm the diagnosis by objective testing. An easy method to evaluate aqueous tear flow is the Schirmer-I test, which is performed by inserting a sterile piece of filter paper in the middle to lateral third of the patient's lower eyelid, and measuring the distance tears elute during a period of 5 minutes. A distance of 5 mm or less is the usual cutoff for abnormally low tear production. Although a Schirmer-I test has an approximately 20% false-negative rate, normal tear flow in the face of ocular foreign body sensations suggests an alternative diagnosis such as blepharitis (see later). Patients with moderate to severe symptoms of dry eyes are usually referred to an ophthalmologist for slit-lamp examination. With a slit-lamp, the ophthalmologist can carefully examine the ocular surface, evaluating for any signs of damage. Instillation of lissamine green or fluorescein dye onto the surface of the eye displays the integrity of the conjunctival and corneal surface. Lissamine green dye stains epithelial surfaces lacking mucin (Figure 73-5), whereas the fluorescein dye targets areas of cellular disruption on the ocular surface. Rose Bengal dye, which stains dead or degenerated cells, is no longer preferred for evaluating the ocular surface because of its toxic effects on the cornea.

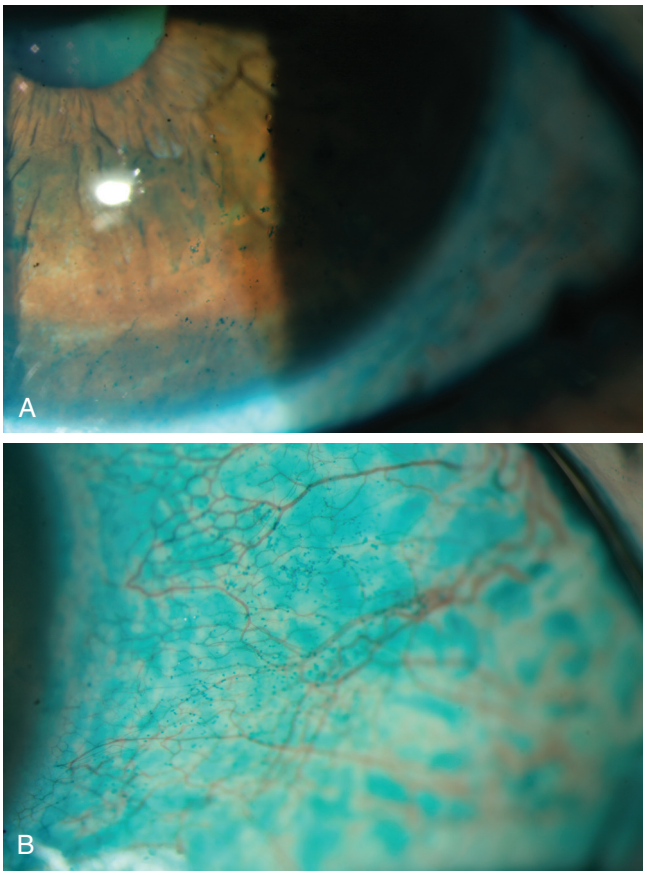

**Figure 73-5** Lissamine staining of a dry eye as shown by slit-lamp examination. **A,** Punctate staining of the cornea. **B,** Punctate staining of the conjunctival epithelium. *(**A** and **B**, Courtesy W. Craig Fowler, MD, Department of Ophthalmology, University of North Carolina at Chapel Hill.)*

Several methods may be used for objective assessment of dry mouth, or xerostomia. Only some patients with xerostomia may show obvious signs of a dry mucosa (e.g., absent sublingual salivary pool, thick and sticky saliva). Sialometry is a method for measuring salivary flow from individual glands (parotid, submandibular, or sublingual) or the mouth as a whole. An unstimulated whole salivary flow rate less than or equal to 1.5 mL/15 min meets the criterion for xerostomia according to the classification criteria developed by the AECG (see Table 73-1). For the collection procedure, patients should keep their heads tilted forward and swallow once to clear the mouth of excess saliva. At this point, the 15-minute collection period is initiated and patients then expectorate as needed, accumulating saliva into a preweighed, 50-$cm^3$ cryovial. Samples are weighed on an analytic balance to determine the volume (1 g = 1 mL) of saliva.

Sialography, another technique for evaluating xerostomia, visualizes radiographic patterns of duct obstruction in

the major salivary glands. It is most useful for differentiating an inflammatory process from a neoplasm. This technique calls for injection of radiographic contrast dye into the salivary duct, followed by serial radiographs to image the pattern of dye flow. A water-based contrast is strongly preferred to an oil-based contrast because the latter may damage the adjacent salivary gland tissue. Sialography is not routinely used in clinical practice because it is an invasive procedure with complications that include duct rupture, pain, and infection. Scintigraphy is a radionuclide technique for measuring salivary gland function. After radiolabeled sodium pertechnetate technetium is injected into the blood, it is absorbed into the salivary gland and secreted into the mouth, allowing for determination of the salivary flow rate. The diagnostic sensitivity and specificity of salivary gland scintigraphy for the diagnosis of primary Sjögren's syndrome has been estimated to be 75% and 78%, respectively.[143] Salivary scintigraphy is not widely available for routine testing.

Ultrasonography and MRI often can detect anatomic abnormalities in the salivary glands of patients with primary Sjögren's syndrome. In comparison with healthy individuals, the detection of parenchymal inhomogeneity by ultrasonography in two or more major salivary gland was found to have a sensitivity of 63% and a specificity of 99% for identifying patients with primary Sjögren's syndrome.[144] Although promising, this technique requires further validation and investigation using appropriate disease controls. MRI with sialography may be more sensitive than ultrasonography for the detection of glandular structural changes,[145] but further studies are necessary to validate this technique as well.

## Labial Salivary Gland Biopsy

Labial salivary gland biopsy has long been considered the gold standard for diagnosing primary Sjögren's syndrome. However, in clinical practice, its use is often reserved for patients in whom the diagnosis remains unclear after a thorough clinical and laboratory evaluation. The biopsy is usually performed by an oral surgeon, otolaryngologist, or other appropriately trained individual. This minor procedure calls for removal of four or more salivary gland lobules through a small incision in the inner lip. A biopsy is considered to be positive if histopathologic analysis shows a focus score of greater than or equal to 1 per 4 $mm^2$ of tissue (a focus is defined as a cluster of 50 or more lymphocytes). With a focus score of greater than or equal to 1 as the cutoff, the sensitivity and specificity of labial salivary gland biopsy for the diagnosis of primary Sjögren's syndrome has been reported at 83.5% and 81.8%, respectively.[20,21] The interpretation of labial salivary gland biopsies is subject to considerable inter-reader variability, depending on the experience of the reader. Therefore it is recommended that the biopsy slides be read by an experienced pathologist or other specialist with an appreciation for the nuances of interpretation.

## Laboratory Evaluation

Most patients with primary Sjögren's syndrome test positive for serum ANAs. In a large study from Spain, ANAs were detected in sera from 85% of patients with primary Sjögren's syndrome.[146] Approximately one-half and one-third of patients with primary Sjögren's syndrome in this study had anti-Ro/SS-A and anti-La/SS-B antibodies, respectively, whereas approximately 50% of patients tested positive for rheumatoid factor. There also appears to be a small subset of patients (<5%) with primary Sjögren's syndrome who test negative for serum anti-Ro/SS-A and/or anti-La/SS-B antibodies, but positive for serum anticentromere antibodies. In one study, patients with serum anticentromere antibodies had a lower prevalence of dry eyes, hypergammaglobulinemia, and anti-Ro/SS-A and anti-La/SS-B antibodies than other patients with primary Sjögren's syndrome, as well as a higher prevalence of Raynaud's syndrome.[147]

Approximately 5% to 10% of patients with primary Sjögren's syndrome have low blood levels of C3 and C4. For example, 9% of the Spanish cohort referred to earlier had low C3 or C4 levels. Approximately the same proportion of patients with primary Sjögren's syndrome have either type II or III cryoglobulinemia or a monoclonal gammopathy.[146] In type II cryoglobulinemia, the monoclonal gammopathy is usually an IgMκ that has rheumatoid factor activity when the patient resides in a Western or European country; patients of Japanese descent express a higher prevalence of IgA and IgG monoclonal gammopathies.[148] Hematologic abnormalities are observed in approximately 5% to 15% of patients with primary Sjögren's syndrome and include leukopenia and thrombocytopenia.

## Approach to Diagnosis

The clinical diagnosis of primary Sjögren's syndrome is highly likely if a patient with symptoms of dry eyes and dry mouth has objective evidence of keratoconjunctivitis sicca and/or xerostomia in conjunction with a positive test for serum anti-Ro/SS-A and/or anti-La/SS-B antibodies. It may not be necessary to obtain histopathologic evidence of salivary gland involvement if the other clinical and laboratory features are consistent with this diagnosis. In some cases, a clinical diagnosis of primary Sjögren's syndrome may be made in the presence of a moderately positive test for ANAs, but in the absence of serum anti-Ro/SS-A and/or anti-La/SS-B antibodies. Because approximately 25% to 50% of patients with primary Sjögren's syndrome test negative for anti-Ro/SS-A and anti-La/SS-B antibodies, a positive test for ANAs may often be the only evidence of an autoimmune process. Serum ANAs of low titer usually have relatively little diagnostic value in this setting unless they are accompanied by anti-Ro/SS-A antibodies.

Biopsy of the labial salivary glands may be warranted in cases in which signs and symptoms of keratoconjunctivitis sicca and xerostomia are not accompanied by convincing serologic evidence of autoimmunity. The labial salivary gland biopsy is used in this scenario to confirm that glandular hypofunction is associated with a chronic inflammatory process and to explore alternative diagnoses, such as sarcoidosis or amyloidosis. In most of these situations, relatively few labial salivary gland biopsies will prove to be positive (focus score ≥1), although a negative result probably reduces the likelihood of primary Sjögren's syndrome to less than 5%.

The diagnosis of primary Sjögren's syndrome in children and adolescents may require special consideration. Compared with adults, children and adolescents are seen more often with recurrent parotitis, which is not included as a criterion in the recent classification schemes derived for adults. It has been shown that adding recurrent parotitis to the AECG classification criteria increases the sensitivity of diagnosing primary Sjögren's syndrome in children and adolescents from 39% to 76%.[34]

## Differential Diagnosis

The differential diagnosis of primary Sjögren's syndrome is broad because of the variety of conditions that also cause dry eyes and mouth, salivary gland enlargement, and a similar profile of extraglandular manifestations (see Table 73-3). It is important to realize that most patients diagnosed with keratoconjunctivitis sicca by an ophthalmologist do not have primary Sjögren's syndrome, despite a deficiency in aqueous tear flow. The etiology of keratoconjunctivitis sicca in these cases is often obscure and presumably related to aging, hormonal changes, or other degenerative processes. Evaporative tear loss secondary to meibomian gland dysfunction is another common cause of dry eyes. In addition, medications with anticholinergic effects contribute to sicca complaints. Because approximately 25% of the general population has symptoms of dry mouth, it is not surprising that dry eyes and dry mouth often may coexist in a patient in the absence of a systemic disease such as Sjögren's syndrome.

Chronic parotitis in association with the sicca complex may result from sarcoidosis. Bilateral diffuse enlargement of the parotid glands from sialadenosis, a non-inflammatory process, occurs in some patients with diabetes mellitus who may also suffer from dry eyes and mouth. In addition, severe hypertriglyceridemia, chronic liver disease, and alcoholism have been associated with sialadenosis and enlargement of the major salivary glands.

Another clinical entity, termed *IgG4-related syndrome*, is emerging as an important consideration in the differential diagnosis of primary Sjögren's syndrome. IgG4-related syndromes are characterized in some cases by high serum levels of IgG4 and tissue biopsies showing a marked infiltration of $IgG4^+$ plasma cells coupled with fibrosis or sclerosis. Compared with primary Sjögren's syndrome, IgG4-related syndromes do not show the same female predominance and are associated with a lower frequency of dry eyes and mouth, arthralgia, and serum ANA positivity, as well as a higher rate of autoimmune pancreatitis.[149]

# TREATMENT

The treatment of primary Sjögren's syndrome aims at reducing the signs and symptoms of dry eyes and dry mouth and controlling the systemic manifestations (Figure 73-6). Sicca complaints may be lessened in general by withdrawal of medications with drying effects. For the treatment of dry eyes, the patient is advised to avoid central heating and air conditioning, windy environments, and medications that reduce tear and saliva production. Tear supplements are available over the counter in various formulations of different viscosities. Low-viscosity tears are administered more often than high-viscosity tear formulations, which are most useful at bedtime for prolonged lubrication during the sleeping hours. Artificial tears are also available with and without preservatives. Preservative-based tears may worsen dry eyes if they are instilled more than four times per day because of their toxic effects on the ocular surface. More frequent instillation of tears warrants use of formulations without preservatives.[150]

An ophthalmic preparation of cyclosporine, 0.05%, (Restasis) has been approved by the U.S. Food and Drug Administration for the treatment of keratoconjunctivitis sicca. In clinical trials, ophthalmic cyclosporine, 0.05%, reduces the signs and symptoms of dry eyes, including a statistically significant improvement in tear flow as measured by the Schirmer-I test. Many patients have trouble tolerating ophthalmic cyclosporine because of its burning effects.

Tears may be conserved by blocking the nasolacrimal drainage channels with temporary or permanent occlusion, a relatively simple procedure performed by an ophthalmologist. This procedure may be performed in patients with persistent symptoms of dry eyes despite use of artificial tears. Plugs are initially placed in the two inferior punctae because 90% of tears drain through these channels. Plugs may be later used to block the two superior punctae. Excessive tearing is the most frequent complication of punctual occlusion, which is the rationale for a trial of temporary blockade with dissolvable collagen plugs before undertaking permanent closure. Long-term punctual closure may be achieved by using silicone plugs, which in some cases are poorly tolerated, or by cauterization or a laser.

Blepharitis often complicates a dry eye state. Patients with blepharitis may benefit from warm compresses and lid scrubs with an eyelid detergent such as Johnson's Baby Shampoo mixed 1:1 with water. Some ophthalmologists avoid the lid scrubs because they can be irritating. More refractory cases of blepharitis may be managed with chronic oral doxycycline therapy. Occasionally, the tear film may contain excessive mucous debris that can be dispersed by instillation of a 10% acetylcysteine ophthalmic solution, a mucolytic agent that can be compounded by a pharmacy.

A dry mouth may be managed by replacing existing saliva or stimulating residual salivary flow. Various over-the-counter preparations of artificial saliva are available containing hypromellose or methylcellulose. However, they provide limited relief in most cases because of their short duration of action. Patients may stimulate salivary flow by sucking on sugarless candy or chewing sugarless gum. Two oral secretagogues are available by prescription that stimulate saliva and tear flow. Pilocarpine (Salagen), which acts by stimulating the M3R, is given at a dose of 5 mg, three to four times daily, and has been shown in controlled clinical trials to improve subjective and objective measures of both dry eyes and dry mouth.[151,152] Cevimeline (Evoxac) also stimulates the M3R and has been similarly shown in trials to improve subjective and objective measures of dry eyes and mouth.[153] Common side effects of these two secretagogues are sweating and flushing, which derive from their mechanism of action. Other possible side effects include visual disturbances, increased urination, nausea, abdominal pain, and diarrhea. Because of their pharmacologic properties, pilocarpine and cevimeline are contraindicated in

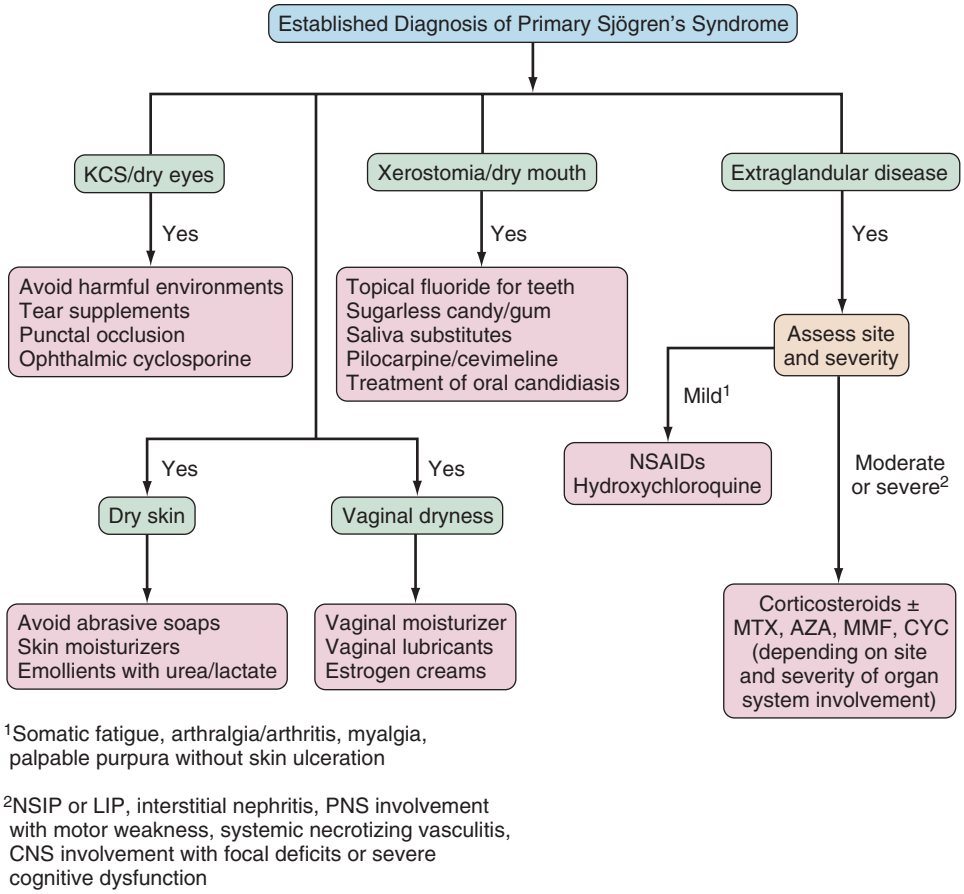

**Figure 73-6** Treatment algorithm for Sjögren's syndrome. The treatment of Sjögren's syndrome usually requires a multidisciplinary approach involving rheumatologists, ophthalmologists, dentists/oral surgeons, otolaryngologists, and other subspecialists, depending on the extent of extraglandular disease. In all cases, it is prudent to minimize the use of medications that can exacerbate the symptoms of dryness, such as antihistamines, antidepressants, muscle relaxers, and other drugs with anticholinergic properties. The treatment of extraglandular disease is individualized according to the site and severity of organ system involvement. The approaches indicated in the algorithm for the treatment of extraglandular disease are not supported by evidence from randomized, controlled trials, but rather from expert opinion based on retrospective case series and clinical experience. AZA, Azathioprine; CNS, central nervous system; CYC, cyclophosphamide; KCS, keratoconjunctivitis sicca; LIP, lymphocytic interstitial pneumonitis; MMF, mycophenolate mofetil; MTX, methotrexate; NSAIDs, nonsteroidal anti-inflammatory drugs; NSIP, nonspecific interstitial pneumonitis; PNS, peripheral nervous system.

patients with iritis, narrow angle glaucoma, and moderate to severe asthma.

Because xerostomia predisposes to dental carries and broken teeth, daily flossing, frequent dental visits, and regular fluoride applications are recommended for prevention purposes. Oral candidiasis, another complication of xerostomia, may be treated for 10 to 14 days with a nystatin elixir, clotrimazole troches, or fluconazole. Clotrimazole cream is beneficial for the treatment of angular cheilitis, which typically accompanies oral candidiasis.

Patients with primary Sjögren's syndrome also suffer from dryness of the lips, skin, and nasal passages. This problem may be addressed by the frequent application of moisturizers, lip balm, and nasal saline spray. The oily content of vitamin E softgel capsules may be used topically on the skin or the lips for its moisturizing effects. Vaginal dryness with dyspareunia is a frequent complaint of women with primary Sjögren's syndrome. This condition may respond to moisturizers and treatment with a topical estrogen cream. Vaginal lubricants may be necessary for treatment of dyspareunia.

Currently, the therapeutic armamentarium of primary Sjögren's syndrome lacks a proven disease-modifying drug. Clinical experience suggests that patient symptoms of fatigue, myalgia, and arthralgia/arthritis may respond favorably to treatment with hydroxychloroquine. A double-blind, parallel group, placebo-controlled trial among 120 patients in France, however, showed that hydroxychloroquine was no better than placebo in reducing dryness, pain, or fatigue.[154] A post-hoc analysis of patients with arthralgia in this study also found that hydroxychloroquine therapy was of no significant benefit in reducing joint pain, but insufficient numbers of patients with synovitis make it difficult to draw any reliable conclusions. In patients with hydroxychloroquine, care is taken to avoid doses exceeding 6.5 mg/kg/day to minimize the risk of retinal toxicity. Annual ophthalmologic examinations are also recommended to monitor for possible retinal complications.

Corticosteroids and other immunosuppressive drugs are often employed for the treatment of organ-threatening extraglandular disease. NSIP and LIP are usually treated with high doses of corticosteroids and other immunosuppressive agents, such as azathioprine, mycophenolate mofetil, or cyclophosphamide. Because virtually no controlled data are available to support the use of these agents

for the treatment of NSIP or LIP, this approach is necessarily empiric and demands judicious monitoring and close follow-up. Bronchiolitis typically improves with high doses of corticosteroids alone, but close follow-up is mandatory for treatment of relapses. Patients who are asymptomatic and have had PFTs showing an isolated mild reduction in DLCO or evidence of small airway disease may be carefully followed up without treatment.

Conservative measures may be the only therapy for a sensory peripheral neuropathy in which medications such as gabapentin and analgesics may help to control the aggravating and painful neuropathic symptoms. High doses of corticosteroids may produce transient improvement in the symptoms of a peripheral neuropathy, but it is unclear if they provide any long-term benefits, and if the benefits outweigh the risks of this treatment. Clinically demonstrable motor loss calls for a more aggressive treatment approach by using corticosteroids and other immunosuppressive agents. Some patients with severe motor involvement may benefit from treatment with intravenous immunoglobulin.

Recurrent lower extremity purpura develops in a minority of patients with primary Sjögren's syndrome. These lesions usually cause burning and stinging and may be associated with lower extremity edema, but they rarely ulcerate. Although moderate to high doses of corticosteroids bring symptomatic relief in most cases, subsequent tapering to low doses and withdrawal usually leads to recurrence of the purpura. Corticosteroid therapy may be avoided in the absence of severe and uncontrollable symptoms or progression to skin ulceration. Support stockings provide symptomatic relief in many cases and can be used in combination with analgesics, antihistamines, or NSAIDs to manage the painful symptoms. The patients are usually left with postinflammatory changes in the skin, which may be an acceptable outcome given the long-term side effects of corticosteroids.

Biologic therapies have been investigated recently for their clinical efficacy and safety in primary Sjögren's syndrome. Infliximab and etanercept, which are TNF inhibitors, have failed in controlled clinical trials to demonstrate therapeutic benefit.[155,156] Rituximab has shown promise in several small trials, including evidence of improvement in fatigue, sicca symptoms and disease activity, although study results were frequently conflicting.[157-160] However, the results of a randomized, double-blinded, placebo-controlled, parallel-group trial involving 120 patients with primary Sjögren's syndrome were unable to show that rituximab provided any significant clinical benefit versus placebo.[160] Other biologics, including belimumab and abatacept, have been tested in small, open-label samples of patients for the treatment of primary Sjögren's syndrome, and others are expected to be evaluated in the near future.[161,162]

EULAR Sjögren's Syndrome Disease Activity Index (ESSDAI) and EULAR Sjögren's Syndrome Patient Reported Index (ESSPRI) are measures developed and validated to assess disease activity and patient-reported outcomes in primary Sjögren's syndrome.[163] These indices have not been used consistently across studies and may be relatively insensitive for detecting improvement in patients with relatively low levels of extraglandular disease activity.

## OUTCOME

Overall mortality is not increased in patients with primary Sjögren's syndrome compared with the general population, although the subgroup of patients with extraglandular disease has an increased risk of morbidity and death. Ioannidis and colleagues[164] showed that, compared with the general population, mortality was not significantly higher in a cohort of 723 patients with primary Sjögren's syndrome. In this study, the patients were subdivided into two groups, types I and II, according to their risk for complications and death. Approximately 20% of the patients fell into the high-risk, type I group, whereas the remainder in the type II group had no increase in the risk for complications or death. In the type I group, patients presenting with palpable purpura and low C4 levels had a higher risk for long-term complications and death.[164] Similar results were found in another study showing no increase in all-cause mortality among individuals with primary Sjögren's syndrome.[165] Hypocomplementemia has been confirmed as a risk factor for adverse outcomes in another cohort of 336 patients with primary Sjögren's syndrome from Spain.[166]

The outcome of primary Sjögren's syndrome is likely to be influenced by disease mechanisms. The labial salivary gland tissue, a target tissue, is readily accessible for study, and new technologies are enabling the discovery of the complex pathways contributing to the aberrant innate and adaptive immune responses in this disease. Genetics and genomics are beginning to provide important clues about disease pathogenesis. An unanswered question is the cause of the glandular hypofunction. It appears that in the earlier stages of disease, glandular damage does not adequately explain the impaired salivary flow, which suggests that autoantibodies, the cytokine milieu, or other mediators are contributing to these functional abnormalities. This knowledge is critical to understanding the potential reversibility of glandular dysfunction and the best targets and timing of therapeutic interventions.

Although primary Sjögren's syndrome cannot yet claim a disease-modifying therapy, much can be done for patients with this disease by effectively managing the sicca component and monitoring for disease complications. Although biologics such as rituximab may yet prove to be useful for treating Sjögren's syndrome, the discovery of new therapeutic targets will shape the future development of new disease-modifying agents. Proof of therapeutic efficacy will require the development of new instruments for quantifying disease activity and damage. Discovery of the first drug with properties of disease modification will be a great progression for the field and will open the door to testing of new therapies in the years to come.

## CONCLUSION

Primary Sjögren's syndrome occurs nearly as often as rheumatoid arthritis and more than 10 times more frequently than systemic lupus erythematosus. Therefore it ranks second in prevalence only to rheumatoid arthritis among the autoimmune disorders in the domain of rheumatology. Many patients with mild forms of primary Sjögren's syndrome probably never come to the attention of the rheumatologist, but rather are managed exclusively by

primary care physicians, ophthalmologists, otolaryngologists, and dentists. Others may never be referred for a diagnosis because of the misperception that little can be done for patients with Sjögren's syndrome. However, primary Sjögren's syndrome is a systemic autoimmune disease that may cause serious organ system involvement. Patients with this disease are also at increased risk low-grade B cell lymphoma. The rheumatologist is aptly trained to accurately diagnose primary Sjögren's syndrome and to lead a multidisciplinary team of specialists who can effectively manage the multisystem complications of this disease.

# SPONDYLOARTHROPATHIES

PART 10

CHAPTER 74

# Etiology and Pathogenesis of Spondyloarthritis

Keith A. Sikora • Gerlinde Layh-Schmitt • Robert A. Colbert

**KEY POINTS**

- Genetics play a major role in the etiology of spondyloarthritis.
- The largest genetic contribution in the population is the B27 allele of human leukocyte antigen-B.
- TNF is a major mediator of inflammation and is currently the principle therapeutic target.
- The IL-23/IL-17 axis plays an important role in pathogenesis of spondyloarthritis.
- New bone formation as well as bone destruction occurs during the course of ankylosing spondylitis.
- There may be a complex temporal relationship between inflammation and new bone formation.

*Spondyloarthritis* refers to a group of diseases with overlapping clinical features and pathogenic mechanisms, yet there are important clinical and outcome differences. Considered to be largely genetic in etiology, environmental triggers in the form of gastrointestinal and genitourinary infections are well recognized for reactive arthritis, but have not been established for ankylosing spondylitis. There is growing interest in whether commensal organisms that are recognized to play important roles in shaping our immune responses also contribute to spondyloarthritis. In the last several years, multiple areas of investigation have converged to provide strong evidence that implicates the IL-23/IL-17 axis in spondyloarthritis pathogenesis. In this chapter we discuss pathogenic mechanisms, drawing largely from studies in ankylosing spondylitis, but whenever possible examine other forms of spondyloarthritis. To fully explain pathogenesis we need to understand what initiates and drives spontaneous chronic inflammation (Figure 74-1), why the enthesis and the axial skeleton are targeted, the role of gastrointestinal inflammation, and the mechanisms driving aberrant bone formation and bone loss, often occurring simultaneously and in close proximity.

## ETIOLOGY OF SPONDYLOARTHRITIS

Spondyloarthritis is a consequence of a complex interaction between genetic polymorphisms and environmental factors. The relative contributions of genes and environment may vary between different forms of spondyloarthritis. For ankylosing spondylitis, heritability is estimated to be more than 90%, suggesting that environmental components are ubiquitous.[1] Gastrointestinal and genitourinary pathogens that are recognized triggers for reactive arthritis (Chapter 76) have no proven role in ankylosing spondylitis. Interestingly, commensal gut microbiota, first shown to be directly involved in the development of human leukocyte antigen (HLA)-B27-associated spondyloarthritis in an animal model more than 20 years ago,[2,3] are now important considerations in the search for the environmental component of human spondyloarthritis.

### Genetics

The class I major histocompatibility complex (MHC) allele, HLA-B27, is the dominant genetic risk factor for spondyloarthritis[4,5] and is present in as many as 90% of individuals with ankylosing spondylitis[6] compared with less than 10% of the population, although frequency varies geographically. Although it is almost necessary to have HLA-B27 for ankylosing spondylitis to develop, it is not sufficient. Less than 5% of HLA-B27 carriers are affected,[7] and despite this striking relationship, it should be emphasized that ankylosing spondylitis occurs in HLA-B27-negative individuals.

Although HLA-B27 has a dominant genetic presence, it accounts for less than 25% of the overall heritability of ankylosing spondylitis.[8] In recent years, genome-wide association studies (GWAS) incorporating thousands of patients and controls have identified at least 30 additional genes or genetic regions that contribute to susceptibility.[9,10] The excitement of these discoveries is tempered by the reality that they account for only an additional 3% of overall heritability.[8] "Missing heritability" is a common problem in complex genetic diseases and may be a consequence of multiple factors. It has been suggested that overall heritability has been overestimated, and thus the proportion discovered may actually be higher,[11] or that the models used to estimate heritability ignore substantial gene-gene interactions (epistasis).[12] Rare variants that are unknown and thus not represented on current single nucleotide polymorphism (SNP) maps may also contribute. Although our understanding of the genetic etiology of ankylosing spondylitis and other spondyloarthritides may be incomplete, the discoveries to date have implicated important immune response

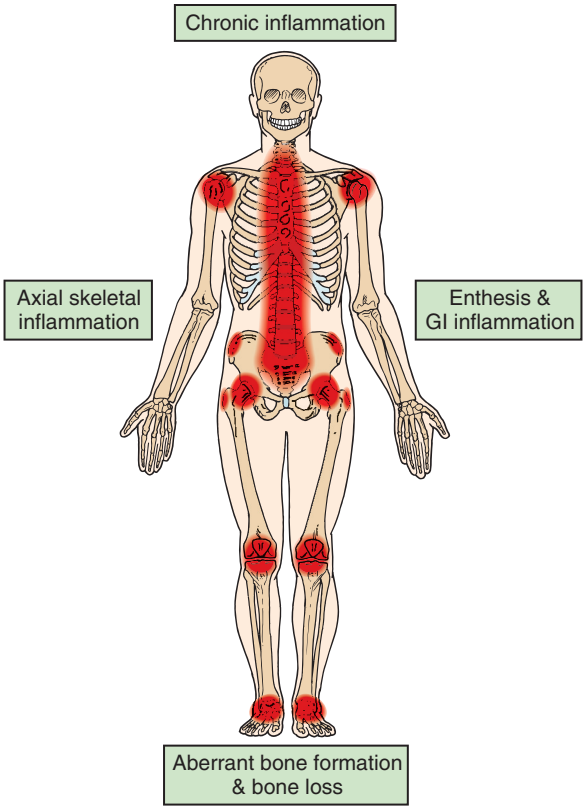

**Figure 74-1** Key components of spondyloarthritis pathogenesis. Chronic inflammation may be revealed systemically, or be primarily local. Entheses are a primary site of inflammation and pathology, with both axial *(red)* and peripheral *(yellow)* sites involved. Root joints (hips and shoulders) are frequently affected. Gastrointestinal (GI) inflammation is common and may be linked to articular manifestations.

pathways and revealed considerable overlap with other immune-mediated inflammatory diseases, most notably inflammatory bowel disease (IBD) (Crohn's disease and ulcerative colitis), psoriasis and psoriatic arthritis, and Behçet's disease[9,10] (Figure 74-2). Relevant pathways and potential mechanisms will be further considered in the context of pathogenesis.

## Environment

Reactive arthritis, defined here as arthritis that follows infection and exhibits features of undifferentiated spondyloarthritis, provides a clear example in which known environmental exposures trigger disease in the susceptible host. The majority of organisms causing reactive arthritis are gastrointestinal pathogens (e.g., *Salmonella spp*., *Campylobacter jejuni* and *Campylobacter coli*, *Yersinia enterocolitica* and *Yersinia pseudotuberculosis*, *Shigella flexneri*, and *Clostridium difficile*), with genitourinary and respiratory infection with *Chlamydia trachomatis* and *Chlamydia pneumonia*, respectively, also implicated. Clinical features, course, and classification of reactive arthritis are covered elsewhere (Chapter 76). For the purpose of this discussion, it is important to emphasize that although cultures are frequently positive for the triggering pathogen at the site of infection, synovial fluid is sterile. For *Chlamydia*-induced reactive arthritis, the situation may be different.[13] Because the organism is difficult to culture even when present, negative results are less informative,[14] and in fact *Chlamydia* can exist and persist inside monocytes or macrophages in the inflamed joint.[15,16] Their presence is best documented by nucleic acid detection by using polymerase chain reaction (PCR), or specific lipopolysaccharides by enzyme-linked immunosorbent assay (ELISA).[15] In the large majority of patients with reactive arthritis, recovery is complete without joint damage or chronic disease. However, some patients will progress to chronic spondyloarthritis including axial involvement with radiographic changes.[17] Thus conceptually, reactive arthritis-associated infectious organisms may serve as a trigger for chronic spondyloarthritis, but this accounts for only a small percentage of those affected. Genetic variants, including HLA-B27, are likely to play a significant role in determining the long-term outcome of reactive arthritis.

The human intestinal tract is colonized by as many as 100 trillion ($10^{14}$) bacteria representing more than 1000 different species.[18] The intestinal microbiome plays a critical role in development of the immune system and maintaining immune cell homeostasis, and is increasingly recognized for its importance in chronic inflammatory diseases.[18] Changes in the gut microbiome, or dysbiosis, are implicated in the pathogenesis of IBD with direct links to predisposing genes involved in innate immunity such as NOD2,[19] an intra-cellular pathogen recognition receptor, and ATG16L1 and IRGM, which regulate intra-cellular bacterial killing via autophagy and GTPase activity, respectively.[20] Dysbiosis in IBD is associated with a loss in diversity and relative reductions in *Firmicutes* and *Bacteroidetes*, and increases in *Enterobacteriaceae*.[21,22] There is evidence that innate immune inflammation may drive gut dysbiosis,[23] although the converse may occur as well, making it difficult to sort out cause and effect. In spondyloarthritis, gut inflammation without overt IBD is common, with as many as 60% of ankylosing spondylitis patients showing subclinical inflammation, and IBD developing in 6.5% during the course of their disease,[24] consistent with overlapping in genetic susceptibility.

From another perspective, as many as 30% of IBD patients may fulfill the criteria for spondyloarthritis,[25] with 11% to 52% exhibiting asymptomatic sacroiliitis, and as many as 10% meeting criteria for ankylosing spondylitis.[24] In both IBD[26] and ankylosing spondylitis,[27] antibodies against gut microbes can be detected, suggesting loss of tolerance.[28] In HLA-B27 transgenic rats that develop spondyloarthritis, animals remain healthy in an environment completely free of known microbes.[2,3] Reintroduction of normal commensal gut bacteria is sufficient to trigger colitis and arthritis.[3] More recently, HLA-B27 transgenic rats were shown to have differences in their gut microbiome, with an increase in *Prevotella spp*. and *Bacteroides vulgatus*, and a decrease in *Rikenellaceae* in the cecum.[29] This is consistent with the idea that one effect of HLA-B27 might be to alter the gut microbiome in a manner that promotes inflammatory disease.[30] Consistent with this hypothesis, patients with HLA-B27$^+$ ankylosing spondylitis exhibit several differences in their terminal ileal microbial communities compared with healthy controls, including a higher abundance of *Prevotellaceae* and *Bacteroidaceae*.[31] However, in both the rat and human studies, it remains unclear whether the microbial content differences are the

cause or the consequence of inflammation. More work needs to be done to better understand the impact of the gut microbiome on spondyloarthritis.

# PATHOGENESIS OF SPONDYLOARTHRITIS

## Functional Genomics

### HLA-B27

Understanding the functional consequences of genetic variants that create susceptibility to immune-mediated inflammatory disease is a key step in unraveling pathogenic mechanisms. For spondyloarthritis, efforts to understand the role of HLA-B27 have been a focus of research since the relationship was initially discovered in the 1970s,[4,5] yet fundamental questions remain unanswered. For example, what aspect(s) of the biology of HLA-B27 that distinguish it from closely related alleles are critical for promoting an immune-mediated inflammatory disease? Is the role of HLA-B27 in undifferentiated spondyloarthritis or reactive arthritis the same as in ankylosing spondylitis? What are the key cell types in which HLA-B27 exerts its effect(s), and does it trigger an abnormal immune response, inflammation, or other biologic effects? Historic perspectives on the biology of HLA-B27 and disease provide more detailed consideration of these questions.[32,33] The three main concepts currently gaining the most attention can be divided into two categories (Figure 74-3). The first encompasses the canonical function of HLA-B27, and suggests that this allele triggers disease through interactions with $CD8^+$ T cells by presenting self-peptides that become the target of an autoimmune response. Based on this hypothesis (arthritogenic peptides),[34] cytotoxic T cell responses to HLA-B27 expressed at various anatomic locations (e.g., entheses, sacroiliac joints, uveal tract) would generate tissue-specific inflammation to explain the spondyloarthritis phenotype. The second category encompasses abnormal features of HLA-B27 such as the tendency for the heavy chain to misfold during assembly in the endoplasmic reticulum (ER) (HLA-B27 misfolding),[35] and for unfolded/misfolded dimers or monomers of HLA-B27 heavy chains free of $\beta_2$m to be displayed on the cell surface (free heavy chain dimers/monomers).[36] These potential mechanisms are not mutually exclusive, and each is fundamentally related to the interaction between the HLA-B27 heavy chain and peptide. The quality (sequence/length) and quantity (supply) of peptides available to, and eventually bound by, HLA-B27 (i.e., peptide sequence and supply) can have substantial effects on its biology. A few aspects of these concepts will be further discussed.

### Arthritogenic Peptides

HLA-B27 and human $\beta_2$m transgenic rats (referred to as *HLA-B27 transgenic rats*) develop highly penetrant enterocolitis and less frequent peripheral and axial arthritis, nail dystrophy, and orchitis/epididymitis.[37] The disease is dependent on the bone marrow compartment,[38] as well as T cells. Surprisingly, $CD4^+$ cells T cells are necessary, whereas $CD8^+$

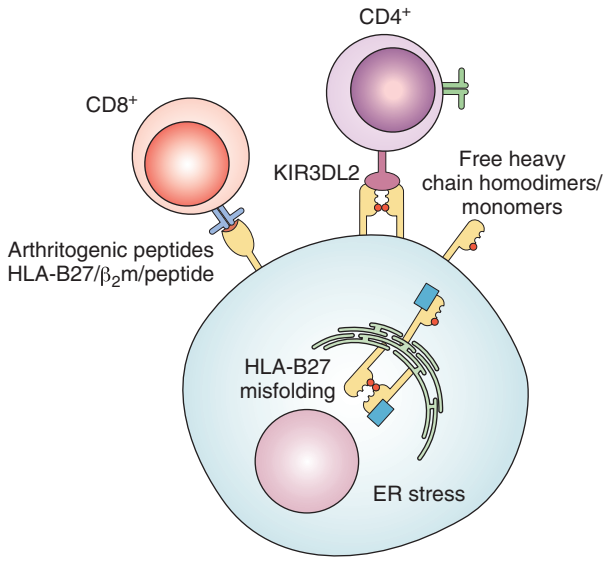

**Figure 74-3** Hypotheses accounting for canonical and noncanonical features of human leukocyte antigen (HLA)-B27 in spondyloarthritis pathogenesis. Arthritogenic peptides presented by properly folded complexes of HLA-B27 with $\beta_2$m and peptide. Free heavy chain homodimers/monomers lacking $\beta_2$m and peptide that engage killer immunoglobulin-like receptor 3DL2 (KIR3DL2) and trigger IL-17 production from $CD4^+$ T cells. Misfolding of HLA-B27 during assembly in the endoplasmic reticulum (ER) generates cellular stress, one consequence of which can be activation of the unfolded protein response. *(Modified from Colbert RA, et al:* Molecular immunology *57:44-51, 2013.)*

T cells that directly interact with HLA-B27 do not cause disease.[39-41] There are striking expansions of $CD4^+$ Th17 cells that express IL-17A, and cells that make IL-17A plus IFN-γ, and to a lesser extent IFN-γ–expressing Th1 cells.[42,43] Thus, arthritogenic peptides do not play a key role in spondyloarthritis in transgenic rats, whereas the IL-23/IL-17 axis is activated.[44] This scenario is consistent with the lack of direct evidence for arthritogenic peptides in human spondylarthritis, and strong evidence for involvement of the IL-23/IL-17 axis.[45] However, it should be emphasized that mechanisms of disease in transgenic rats could differ from those in humans. Although it seems unlikely that entirely distinct mechanisms would result in the striking phenotypic overlap between rat and human spondyloarthritis, and the common elements of pathogenesis revealed to date, arguments supporting a possible role for arthritogenic peptides persist and should be considered.[46,47]

## HLA-B27 Misfolding

The unique peptide-binding specificity of HLA-B27 also promotes misfolding of newly synthesized heavy chains.[35,48] Misfolding of membrane bound or secreted proteins has consequences that can range from loss-of-function to gain-of-function. Some of the latter effects are caused by the generation of stress in the ER, enhanced cell death, and activation of autophagy.[49] The majority of work on HLA-B27 misfolding has focused on the generation of ER stress and activation of the unfolded protein response (UPR) although other consequences are possible.[50,51] This is readily detectable in HLA-B27 transgenic rats that have multiple copies of the transgene, but only in some cell types and under certain conditions,[52] and not in rats that overexpress HLA-B7.[50] ER stress and UPR activation promote Toll-like receptor-mediated IFN-β and IL-23 induction[32,42] via the UPR target gene *Ddit3* (CHOP),[53] providing a potential link between HLA-B27 and $CD4^+$ Th17 cell-driven disease. Evidence of UPR activation in cells or tissues from patients with HLA-B27 and spondyloarthritis has been more variable. Macrophages from synovial fluid express more of the UPR target gene *Hspa5/BiP*,[54] however, this has not been evident in macrophages derived from peripheral blood monocytes.[55,56] UPR activation was reported in bulk peripheral blood mononuclear cells (PBMCs) isolated from ankylosing spondylitis patients but not in HLA-B27-negative healthy controls,[57] whereas others have not found evidence of UPR target gene overexpression.[58] Differences in methodology and experimental conditions between these studies need to be explored.

In ileal mucosal tissue from ankylosing spondylitis patients with subclinical gut inflammation, autophagy was activated without the UPR being apparent.[59] Colocalization of free HLA class I heavy chains with HRD1 (encoded by SYVN1), a ubiquitin ligase involved in ER-associated degradation (ERAD) of misfolded HLA-B27,[60] suggested that in gut tissue misfolding might be associated with ERAD and activation of autophagy precluding the need to activate the UPR. Inhibition of autophagy increased the frequency of cells expressing IL-23p19, suggesting that inhibition of autophagy might increase IL-23 production, as has been reported.[61] Autophagy does not appear to be activated in synovial tissue from ankylosing spondylitis patients.[62] Taken together, the evidence is consistent with the idea that the consequences of HLA-B27 misfolding are cell type-dependent, and may impact ER function only under certain conditions such as during upregulation when misfolded heavy chains can accumulate.[52] Further work with human cells containing a single copy of HLA-B27 is needed to determine whether misfolding can promote IL-23 production through the UPR and/or autophagy, or whether other biologic effects emerge.

There is also evidence that dendritic cells from HLA-B27 transgenic rats are dysfunctional, exhibiting altered class II MHC expression and viability, resulting in preferential loss of a tolerogenic $CD103^+$ population.[63-66] The dendritic cells have the property of reduced immune synapse formation and tend to promote Th17 development,[43] and thus may play a role in disease promotion. The molecular property of HLA-B27 that is responsible for these effects remains unclear.

## Free Heavy Chain Dimers and Monomers

Another unusual feature of HLA-B27 is its tendency to exist on the cell surface as $\beta_2$m-free heavy chains, either in the form of disulfide-linked homodimers or monomers,[36,67] in addition to the trimolecular complexes containing peptide and $\beta_2$m that predominate. Homodimers are "aberrant" forms of HLA-B27 that are covalently linked via the unpaired cysteine at position 67. They form during endosomal recycling of cell surface complexes and do not appear to emerge from the pool of misfolded dimers in the ER.[68,69] Free heavy chain monomers may arise from loss of peptide and $\beta_2$m on the cell surface. Suboptimal (low affinity)

peptides that are loaded in antigen-processing pathway-deficient cells dissociate more readily from HLA-B27, and promote the formation of free heavy chain monomers as well as homodimers.[48]

HLA-B27 homodimers can trigger leukocyte receptors in the killer immunoglobulin receptor (KIR) and leukocyte immunoglobulin-like receptor (LILR) families.[69] KIRs are highly polymorphic cell surface receptors expressed on natural killer (NK) cells, and subsets of $CD4^+$, $CD8^+$, and NK T cells.[70] Different forms of LILRs are expressed on NK, B, T and dendritic cells (LILRB1), or monocytes and dendritic cells (LILRB2). Both KIRs and LILRs bind class I MHC molecules in an allele-specific fashion, and certain variants bind HLA-B27 dimers. While many interactions have been demonstrated, of particular importance is the binding of KIR3DL2 because it does not interact with properly folded forms of HLA-B27. $KIR3DL2^+$ $CD4^+$ T cells and NK cells are expanded in the blood and synovial fluid of spondyloarthritis patients,[71,72] and can be triggered to produce IL-17 after encountering cells that express large amounts of HLA-B27 dimers on the cell surface.[72] IL-17 production is inhibited in the presence of antibodies that bind to HLA-B27 dimers or KIR3DL2, indicating the need for direct interaction. Free heavy chain monomers can interact with KIRs and LILRs, although the relative contributions of free heavy chain monomers and dimers to $CD4^+$ T cell stimulation is unclear. Many of these studies have been performed by using engineered tetramers of homodimers, or cells transfected with HLA-B27 that overexpress cell surface homodimers because of a deficiency in the class I assembly pathway, and thus the extent to which cells derived from spondyloarthritis patients trigger KIR3DL2-expressing $CD4^+$ T cells in vivo remains an important consideration.

## ERAP1

Variants of endoplasmic reticulum aminopeptidase-1 (ERAP1), which encodes an important component of the class I MHC antigen processing and assembly pathway, are associated with ankylosing spondylitis[73,74] as well as other diseases including those with class I MHC associations.[75,76] ERAP1 trims N-terminal amino acids from peptides in the ER that are destined to be displayed by class I MHC molecules.[77-79] It is also involved in cytokine receptor shedding, regulation of angiogenesis and blood pressure, and macrophage activation.[80-83] The genetic effect of ERAP1 in ankylosing spondylitis is limited to $HLA\text{-}B27^+$ individuals, in which variants reported to be loss-of-function were associated with protection.[74] However, recent studies have demonstrated functionally distinct ERAP1 haplotypes (referred to as *allotypes*).[84,85] When allotypes associated with ankylosing spondylitis were assessed, they were poor at generating optimal peptides for HLA-B27 and other class I MHC molecules, indicating that loss-of-function confers risk rather than protection.[85] These and other data strongly suggest that the role of ERAP1 in trimming peptides in the ER is critical for its association with ankylosing spondylitis. However, the functionally different ERAP1 allotypes that influence peptide supply are likely to alter various properties of HLA-B27 from folding and assembly to cell surface dimerization,[48] as well as the presentation of individual epitopes to T cells.[86,87]

## Genetic Susceptibility Distinct from the Major Histocompatibility Class I Pathway

IL-23 receptor gene *(IL23R)* variants associated with inflammatory bowel disease,[88] psoriasis,[89] and ankylosing spondylitis[73] have implicated the IL-23 signaling pathway in distinct but related diseases.[45] IL-23 is a critical cytokine for promoting proliferation and differentiation of $CD4^+$ Th17 T cells.[90,91] It also stimulates IL-17 production from Th17 as well as innate immune cells, including γδ T cells, certain NK cells, invariant NK T cells, Paneth cells, mast cells, and lymphoid tissue inducer cells, and a population of $CD4^-$/$CD8^-$/$CD3^+$ T cells.[92,93] The *IL23R* SNP (rs11209026) that is most strongly associated with protection from ankylosing spondylitis and IBD produces a nonsynonymous Arg381Gln substitution that reduces IL-23 responsiveness.[94] Subsequent GWAS in ankylosing spondylitis have identified additional genes that may influence IL-23 production *(CARD9, IL12B, PTGER4)*, the number or frequency of IL-23 responsive cells *(IL6R, IL27)* and IL-23 signaling (*TYK2* and *STAT3*, in addition to *IL23R*), have strengthened the evidence that the IL-23/IL-17 axis is involved in susceptibility[10,74,95,96] (Figure 74-4). The functional impact on immune cell development and function of most individual genetic variants or risk haplotypes remains to be worked out. However, combinatorial effects of risk/susceptibility alleles in a diverse population of spondyloarthritis patients revealed that the protective *IL23R* variant was associated with decreased expression of Th17 and Th1 genes, whereas patients with greater numbers of IL-23/IL-17 pathway risk SNPs exhibited greater expression.[97]

## IL-23 and the Spondyloarthritis Phenotype

Systemic expression of IL-23 in mice causes peripheral and axial enthesitis and sacroiliitis, and entheseal new bone formation in the absence of any initial synovial inflammation. This led to the discovery of a unique population of $CD3^+$/$CD4^-$/$CD8^-$ T cells situated in the enthesis that also express the "Th17" transcription factor RAR-related orphan receptor-γt (ROR-γt), and the IL-23 receptor.[93] In response to IL-23, the entheses produce IL-6, IL-17, IL-22, and CXCL1, consistent with the Th17-like phenotype of the T cells. IL-22 was implicated in promoting osteoblast mediated bone remodeling (Figure 74-5), although the cellular target of IL-22 remains to be determined. A similar phenotype that also exhibits gut inflammation can be induced in ZAP-70 mice when animals are treated with microbial β-glucans.[98] Beta-glucans such as curdlan and zymosan are microbe-associated molecules that are potent inducers of systemic IL-23 through the dectin-1/CARD9 pathway. SKG mice accumulate autoreactive $CD4^+$ Th17 T cells because of a mutation in the ZAP-70 T cell receptor subunit that alters T cell selection, and they overproduce Th17 cytokines in response to IL-23.[98] Together, these models demonstrate that IL-23 can produce a remarkable phenocopy of human spondyloarthritis and the potential importance of innate immune signaling stimulated by microbial products. They also suggest ways in which crosstalk between the innate immune system and adaptive $CD4^+$ Th17 T cells can be important. The existence of entheseal $CD3^+$/$CD4^-$/$CD8^-$/ROR-$\gamma t^+$/$IL\text{-}23R^+$ T cells provides a novel explanation for

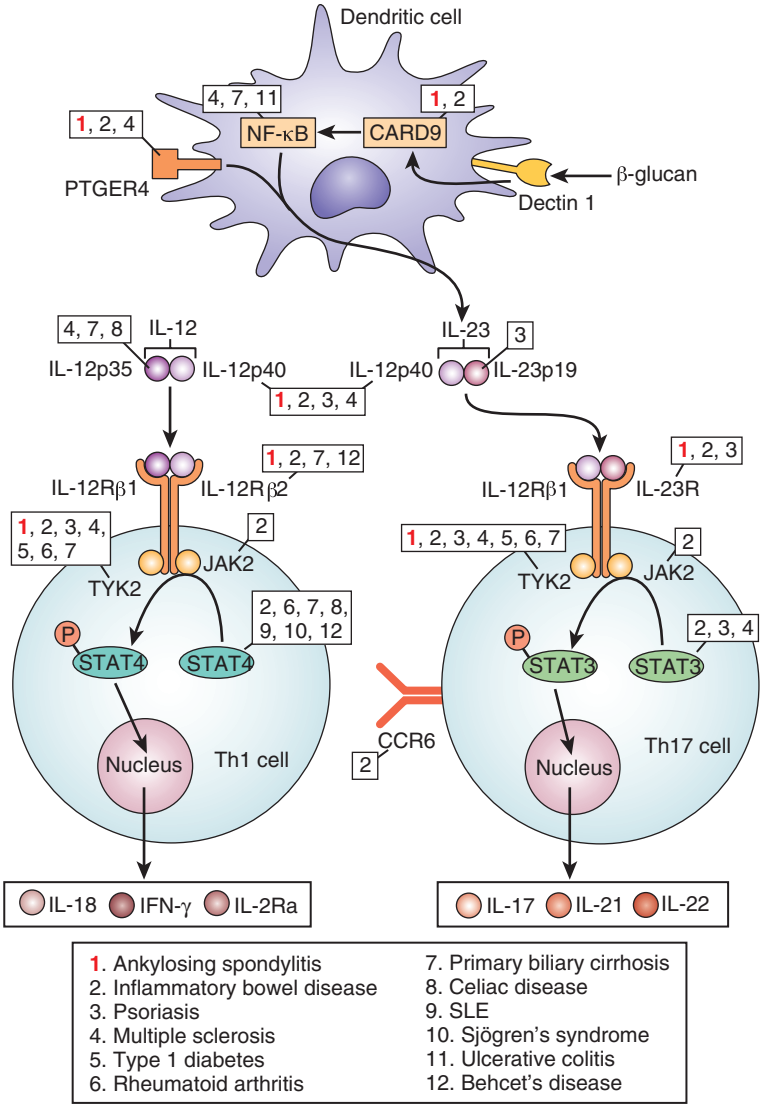

**Figure 74-4** Components of the IL-23/IL-17 axis and Th1 pathway showing genes implicated in pathogenesis of several immune-mediated inflammatory diseases. Multiple components of the IL-23 production and IL-23 receptor (IL-23R) response pathway show significant genetic associations. In addition to conventional T helper (Th1) and Th17 lymphocytes, it is now recognized that other T cells and innate immune cells are highly responsive to IL-23 and likely influenced by genetic factors. These various cell types are candidates to have key roles in various diseases. *Red circles* highlight ankylosing spondylitis associations. **Figure 74-5** IL-23 drives entheseal-resident T cells in the pathogenesis of spondyloarthritis in mice. Various pathways may lead to increased IL-23 expression. IL-23 can activate resident T cells within the enthesis, which can promote local inflammation and bone remodeling through a variety of cytokines, including IL-17 and IL-22. These actions may culminate in new bone formation and ankylosis. TNF, Tumor necrosis factor; UPR, unfolded protein response. *(From Sherlock JP, Joyce-Shaikh B, Turner SP, et al: IL-23 induces spondyloarthropathy by acting on ROR-gammat+CD3+CD4−CD8− entheseal resident T cells.* Nat Med *18:1069-1076, 2012; Macmillan Publishers Ltd.)*

how the unique spondyloarthritis phenotype might be generated in early disease, without invoking $CD8^+$ T cell-mediated autoreactivity or other IL-17-producing cells.

### Cytokines and Cytokine-Producing Cells in Spondyloarthritis

Considerable evidence from human studies indicates that the IL-23/IL-17 axis is activated in spondyloarthritis.[45] Serum and synovial fluid levels of IL-17 and/or IL-23 can be elevated,[99-102] although serum IL-23 correlates poorly with disease activity in spondyloarthritis compared with rheumatoid arthritis.[103] $CD4^+$ Th17 cells, including those that express KIR3DL2, may be increased in number or frequency in the peripheral blood and synovial fluid of spondyloarthritis patients,[72,104-108] consistent with cytokine data. It should be noted that other studies have not found increases in $CD4^+$ Th17 cells,[109-111] including those that express KIR3DL2,[108] and in one study more IL-23$R^+$ γδ T cells were observed.[111] Variability in spondyloarthritis subtypes, disease duration, and disease activity may be important factors that contribute to these differences. Perhaps more important in spondyloarthritis is the consideration that peripheral blood and synovial fluid do not reflect pathologic processes active in the sacroiliac joints, vertebral bodies, facet joints, and bone marrow adjacent to these axial inflammatory lesions. This is exemplified by TNF, in which serum levels are not uniformly increased in spondyloarthritis[112,113] and can even be lower in ankylosing spondylitis than healthy controls,[114] yet this cytokine is overexpressed in actively inflamed sacroiliac and hip joints,[115,116] and it is a major therapeutic target. Several studies have documented expression of IL-17 and IL-23 at sites of inflammation in spondyloarthritis. Mast cells in the synovium of patients with peripheral spondyloarthritis contain IL-17,[117] whereas in ankylosing spondylitis neutrophils (myeloperoxidase $[MPO]^+/CD15^+$) and mononuclear cells express IL-17 in facet joints.[109] IL-23 overexpression in inflamed ileum and bone marrow has also been documented.[118,119] In ileal biopsies from patients with subclinical inflammation, IL-23 localized to infiltrating monocytes and Paneth cells,[118] whereas in the marrow of spinal facet joints IL-23 was predominantly localized to myeloid precursors ($MPO^+/CD15^-$), and to a lesser extent in $CD68^+$ or $CD163^+$ macrophages.[119] Evidence from GWAS, animal models, and translational studies in humans, together with emerging results from clinical trials blocking IL-17A[120] and IL-12/23,[121] provides strong support the importance of the IL-23/IL-17 axis in spondyloarthritis pathogenesis.

## STRUCTURAL DAMAGE IN ANKYLOSING SPONDYLITIS

Until this point the focus has been on mechanisms that promote chronic inflammation in joints, entheses, and the gut in spondyloarthritis. Structural damage is an important contributor to morbidity in ankylosing spondylitis, and deserves special consideration. Although erosions occur, and in the sacroiliac joint may be seen as irregular margins or joint space widening on plain radiographs, they are often limited in severity. Bone inflammation, or osteitis, is frequently visualized as bone marrow edema and can lead to significant vertebral trabecular bone loss even in early disease,[122] and contributes to increased fractures.[123] Bone loss in ankylosing spondylitis is problematic, but the principal causes of structural damage are aberrant bone formation that results in fusion of the sacroiliac and zygapophyseal joints, and syndesmophytes that eventually bridge vertebral bodies and result in ankylosis.[124] The principal paradox in ankylosing spondylitis is that bone loss and bone formation, often regulated by opposing signals, occur simultaneously and frequently in juxtaposition. This is most notable in and around vertebral bodies. Aberrant bone formation is not explained by gross differences in the inflammatory infiltrate in spondyloarthritis, which is similar to more erosive arthritic conditions.[125]

### Bone Homeostasis and Aberrant Bone Formation

Bone homeostasis is a tightly regulated balance between osteoclasts responsible for bone resorption and osteoblast lineage cells that form bone. Several factors may disrupt this balance in spondyloarthritis, and thus are worth considering in greater detail. Osteoclasts are derived from bone marrow hematopoietic stem cells that differentiate into monocytes and then macrophages under the influence of macrophage-colony stimulating factor (M-CSF) and receptor activator of nuclear factor-κB (NF-κB) ligand (RANKL).[126] Pro-inflammatory cytokines such as TNF, IL-17, IL-6 ,and IL-1 promote osteoclastogenesis and bone degradation either directly or through effects on RANKL expression in other cells,[127] whereas IFN-β is an inhibitor.[128] Osteoprotegerin (OPG) also inhibits osteoclastogenesis by direct inhibition of RANKL. Analysis of tissue from patients with ankylosing spondylitis reveals evidence of persistent osteoclast activity and bone destruction, even in long-standing disease.[129] Increased osteoclast precursors in peripheral blood of patients with ankylosing spondylitis has been noted[130] and could be caused in part by a pro-osteoclastogenic milieu with a reduced OPG/RANKL ratio in the serum.[131] Other pro-osteoclastogenic cytokines may contribute, and HLA-B27 misfolding in transgenic rats promotes osteoclast formation through increased IL-1α production.[132]

In contrast to osteoclasts, osteoblasts are derived from mesenchymal stem cells. Several osteoblast lineage cells are involved in bone and cartilage formation (e.g., mesenchymal progenitors, preosteoblasts, mature osteoblasts, and osteocytes). They are poorly defined histologically but express different transcription factors critical to their developmental programs.[126] Bone formation and growth occur through two different processes. Endochondral bone formation is characterized by bone marrow-derived mesenchymal stem cells differentiating into hypertrophic chondrocytes that form cartilage tissue matrix. Mesenchymal cells that differentiate into osteoblasts are attracted to the matrix, which is eventually replaced by bone matrix from osteoblasts. During membranous bone formation, mesenchymal cells differentiate directly into osteoblasts that then produce calcifying bone matrix. Both endochondral and membranous or direct bone formation are involved in the pathogenesis of ankylosing spondylitis.[133-137] New bone formation, often referred to as *osteoproliferation*, has been characterized as a tissue remodeling process as opposed to merely bone

proliferation,[138] but also differs from classic remodeling in which osteoclast and osteoblast activity are tightly balanced. New bone is thought to originate from the enthesis and periosteum, and primarily involves the sacroiliac, zygapophyseal and costovertebral joints, and vertebral bodies. Syndesmophytes grow along the vertical axis between edges of vertebral bodies by apposition of new bone resulting in fusion of the vertebrae. There can be ongoing loss of trabecular matrix in vertebral bodies, whereas cortical bone is simultaneously added to growing syndesmophytes at the vertebral margins, implying that local factors must be important.

Bone development is regulated by several soluble factors, including bone morphogenetic proteins (BMPs), wingless-related integration site proteins (Wnts), hedgehog, and fibroblast growth factors (FGFs). BMP and Wnt signaling pathways have been implicated in aberrant bone formation in spondyloarthritis,[137] and will be discussed in more detail. BMPs stimulate endochondral bone formation through effects on chondrocyte differentiation and hypertrophy.[139] They are also important in early developmental processes and homeostasis of other organ systems.[140,141] BMPs are antagonized by noggin, which is secreted by chondrocytes, and osteocyte-derived sclerostin. Wnt family proteins are also important regulators of early bone development and homeostasis, and similar to BMPs, are critical for the development of other organs and tissues.[142,143] Wnts are expressed by osteocytes and can be regulated by mechanical stresses. They stimulate bone formation by direct effects on osteoblasts, and also influence cartilage homeostasis.[144] Wnts signal through a receptor known as frizzled, which is regulated by binding to low-density lipoprotein receptor-5 (LRP5) and LRP6. Wnt signaling is inhibited by sclerostin, which binds to LRP5, and thus sclerostin inhibits bone formation.[145] Other Wnt antagonists include Dickkopf-1 (Dkk1), which, similar to sclerostin, binds to LRP5, and secreted frizzled-related protein (SFRP), which binds directly to Wnt proteins.

BMP signaling has been linked to excessive bone formation in DBA/1 mice that develop spontaneous peripheral ankylosing enthesitis.[146] Administration of the BMP antagonist noggin was able to reduce and prevent bone formation and peripheral joint ankylosis in BDA/1 mice. Enhanced BMP signaling in a biopsy from a patient with Achilles enthesitis and new bone formation suggests that increased BMP signaling might be linked to excessive bone formation in humans with spondyloarthritis. The Wnt pathway has also been implicated in aberrant bone formation in spondyloarthritis through Dkk1 and sclerostin. Dkk1 and sclerostin are upregulated by TNF and in a peripheral inflammatory arthritis model, inhibiting Dkk1 reduced bone destruction and promoted osteophyte formation, revealing its normal role in limiting destructive damage and even excessive repair.[147] In another animal model of spondyloarthritis in which engineered overexpression of TNF causes sacroiliitis, Dkk1 inhibition promoted sacroiliac joint fusion.[148] Abnormally low levels of Dkk1 were reported in patients with ankylosing spondylitis,[147] and although Dkk1 levels seem to go down after TNF inhibition in patients with rheumatoid arthritis, this was not the case in ankylosing spondylitis.[148] Higher levels of Dkk1 were associated with protection from syndesmophyte formation in ankylosing spondylitis.[149] There is also seemingly contradictory evidence that Dkk1 is elevated in ankylosing spondylitis, but in this study it was dysfunctional.[150] Differences in methods used to detect Dkk1 may be responsible for the discrepancy and need to be resolved.[151] Overall, these data suggest Dkk1 (or lack of it) could play an important role in structural damage in ankylosing spondylitis.

Sclerostin, another Wnt pathway inhibitor, has also been reported to be lower in patients with ankylosing spondylitis, which correlates with radiographic progression.[152] Reduced sclerostin levels were confirmed in a recent study, whereas Dkk1 was not low except in individuals with the greatest structural damage.[153] This study revealed elevations in Wnt-3a that correlated positively with structural damage, providing the first demonstration that Wnt agonists might also be useful biomarkers. Interestingly, autoantibodies recognizing noggin and sclerostin that could promote osteoproliferation and structural damage in ankylosing spondylitis were recently noted.[154]

## Inflammation and New Bone Formation in Spondyloarthritis

The relationship between inflammation and new bone formation in spondyloarthritis continues to be the subject of debate.[155] The argument that these are distinct, uncoupled processes is predicated in large part on studies that show no benefit of TNF inhibitors in patients with ankylosing spondylitis,[156,157] and from the ankylosing enthesitis DBA/1 mouse model in which clear evidence exists that TNF inhibition has no impact on entheseal new bone formation.[158] The opposing view that inflammation is in some way coupled with new bone formation is now supported by two studies that compare cohorts of patients treated with TNF inhibitors with cohorts who were not exposed.[159,160] The first study provides evidence for reduced radiographic progression with use of TNF inhibitors and suggests that early initiation and longer follow-up are important variables.[159] Consistent with these data, a long-term follow-up study of TNF inhibitor treated and untreated cohorts revealed fewer new syndesmophytes and lower damage scores (Modified Stoke Ankylosing Spondylitis Spine Score) after 8 years in patients on TNF inhibitors, whereas no differences were seen after the first 4 years.[161] Both of these studies from patients treated with TNF inhibitors are consistent with the small reduction in radiographic progression seen with continuous NSAID use and suggest a link between inflammation and aberrant bone formation.[162] The DBA/1 ankylosing enthesitis model, in which TNF inhibitors had no effect on the incidence or severity of joint ankylosis, may simply be an example of a mouse model that reflects poorly on what happens in humans.

A 2-year longitudinal MRI study suggests that resolution of inflammation (bone marrow edema) and erosions around the sacroiliac joints are independently associated with development of "backfill" and "fat metaplasia" lesions on MRI. Fat metaplasia was used to describe high T1 signal intensity (fat signal) in regions of noneroded bone marrow, whereas backfill referred to a fat signal in areas where erosions had occurred. Reduction in erosions and increased fat metaplasia were associated with ankylosis. These findings were used to support a model in which ankylosis develops after repair of erosions, with fat metaplasia and backfill seen

as important intermediate steps.[163] In another study of vertebral lesions, inflammation and fatty degeneration at baseline and fatty degeneration at 2 years even in the absence of inflammation at baseline, were both associated with syndesmophyte formation at 5 years in patients on TNF inhibitor therapy.[164] Although this evidence contradicts the idea that inflammation is a prerequisite for new bone formation, other studies have shown that MRI is insufficiently sensitive to detect all inflammation, at least in the sacroiliac joint.[165] Thus important limitations exist in the interpretation of lack of inflammation in imaging studies. Efforts in this area are significantly hampered by the location of lesions in axial spondyloarthritis and inherent difficulties in accessing the tissue. Despite the encouraging results suggesting that TNF inhibitors may impede progression of structural damage, it is important to note that results to date suggest that syndesmophytes still form in TNF inhibitor treated patients. This evidence implies that suppression of inflammation with these agents does not completely prevent new bone formation. A clear need exists for a better understanding of pathogenesis and to identify ways of stopping and preventing structural damage.

Several genes identified by GWAS (*ANTXR2*, *PTGER4*, *HAPLN1*, *EDIL3*, and *ANO6*)[74,166] have the potential to impact bone formation in ankylosing spondylitis.[124] For example, *PTGER4* encodes a receptor for prostaglandin E2, an inflammatory mediator that promotes mineralized bone nodule formation. *ANTXR2* encodes the anthrax receptor, also known as capillary morphogenesis protein 2 (CMG2). It interacts with the low-density lipoprotein receptor-6 (LRP6) and LRP5, both of which are involved in regulating Wnt signaling. *HAPLN1* encodes hyaluronan and proteoglycan link protein 1 (also known as Crtl1), which is implicated in endochondral bone formation. An SNP in *HAPLN1* has been associated with osteophyte formation and disc degeneration.[167] In addition, *ANO6* is expressed in osteoblasts as well as other cell types, where it is required for normal mineralization.[168] Once disease-associated SNPs or haplotypes are identified, functional studies can be initiated that may shed light on the role of these genes in ankylosing spondylitis.

## CURRENT AND FUTURE THERAPEUTIC TARGETS IN SPONDYLOARTHRITIS

### Targeting the IL-23/IL-17 Axis

TNF is well established as an important therapeutic target in ankylosing spondylitis. Surprisingly little is known about its predominant cellular source, the mechanisms that drive its production in spondyloarthritis, or whether genetic factors influence the cellular response to this cytokine. TNF may be a relatively early upstream trigger in early disease, and/or a mediator of downstream mechanisms with positive and negative feedback loops in more chronic inflammation that influence its overall effect.[169] The accumulated evidence implicating dysregulation of the IL-23/IL-17 axis in spondyloarthritis is strong, and early results from clinical trials of both IL-17A and IL-23/IL-12 blockade are encouraging.[120,121] Targeting this axis may offer additional options and therapeutic benefit, with the potential to positively impact long-term outcomes for patients with spondyloarthritis.

CHAPTER 75

# Ankylosing Spondylitis

Sjef van der Linden • Matthew Brown • Tony Kenna • Walter Maksymowych • Philip Robinson

**KEY POINTS**

- **The spectrum of axial spondyloarthritis comprises both ankylosing spondylitis (AS) according to the modified New York criteria and nonradiographic axial disease.**
- **Magnetic resonance imaging of the sacroiliac joints may show inflammation before structural changes appear on conventional radiographs.**
- **Nonradiographic axial spondyloarthritic disease occurs approximately 2 to 3 times as often as AS according to modified New York criteria, and may show comparable disease activity.**
- **Nonradiographic axial spondyloarthritis is more heterogenous than AS according to modified New York criteria, human leukocyte antigen (HLA)-B27 prevalence varies widely, there is no male preponderance, and patients may or may not progress to radiographic sacroiliitis. The natural history of nonradiographic axial spondyloarthritis is not well known.**
- **Applying classification criteria for axial spondyloarthritis as a diagnostic tool should be avoided to reduce the risk of a false-positive diagnosis of axial spondyloarthritis.**
- **In many populations, AS occurs in 1% to 3% of *HLA-B27*$^+$ individuals. The disease is more common, occurring in approximately 10% of first-degree relatives of *HLA-B27*$^+$ AS patients.**

Ankylosing spondylitis (AS) belongs to the group of diseases known as the *spondyloarthropathies* or, better, *spondyloarthritides*. This group of disorders constitutes a family of related but heterogeneous conditions, rather than a single disease with different clinical manifestations[1] (Tables 75-1 and 75-2).

Radiographic sacroiliitis is considered a hallmark of AS. The inflammation of the sacroiliac (SI) joints and the spine eventually may lead to bony ankylosis. Spinal ankylosis tends to appear in late stages of the disease and does not occur in many patients with mild disease.

Many patients with AS have onset of back pain during the third decade of life. It takes, on average, 6 to 8 years from the onset of back pain until a clinician establishes a definite diagnosis of AS. This diagnostic delay in the majority of patients results mainly from the relatively late appearance of definite radiographic sacroiliitis on conventional plain radiographs.[2,3] Active sacroiliitis on MRI has been shown to predict the later appearance of sacroiliitis on radiographs.[4] Thus many patients at an early stage of AS typically are seen with characteristic clinical symptoms of AS, but definite sacroiliitis may not show up on radiographs. Therefore they may not be classified with AS according to the modified New York criteria.[5] In such patients with suspected early-stage AS, sacroiliitis may best be detected on MRI.[3] Radiographic sacroiliitis (i.e., structural damage of SI joints) may develop in a substantial proportion of such patients with time (approximately 20% to 25% over a period of 15 years) and will progress to definite AS, fulfilling the modified New York criteria.[5,5a] This finding also implies that a significant proportion of patients will remain at this (nonradiographic) stage of disease, with inflammation of SI joints at some point, but without radiographically detectable damage during the subsequent years.[4] Therefore, to describe these patients correctly, the term *early AS* has been dropped in favor of the more fitting term *nonradiographic axial spondyloarthritis* (nr-axSpA)[6] (Figure 75-1). The term *axial spondyloarthritis* (axSpA) comprises both nonradiographic AS and classic AS (according to the modified New York criteria). The total prevalence of axSpA has been estimated at two to three times that of AS according to the modified New York criteria.[7-9] Contrary to the modified New York criteria, there is no male preponderance for AS among patients with nr-axSpA.[8] In population-based studies, human leukocyte antigen *(HLA)-B27* prevalence varies widely (from 20% to 97%) depending on how many patients were included.[8,9] Such patients may have active disease that needs appropriate treatment. The efficacy of conventional disease-modifying anti-rheumatic drugs (DMARDs) in these patients is largely unknown. At the group level, these patients tend to respond less favorably to treatment with TNF inhibitors than AS patients by modified New York criteria.[10] The course and natural history of axSpA without radiographic sacroiliitis is not yet well known. This chapter focuses on radiographic AS. Although this disease may be more homogenous than the full spectrum of axSpA, many aspects also apply to patients with nonradiologic AS or axSpA.[11,12]

## CLASSIFICATION

### Criteria for Ankylosing Spondylitis and Axial Spondyloarthritis

Classification criteria are intended for clinical and epidemiological studies and also for research on the etiopathogenesis of diseases. Such criteria should create homogenous groups of patients who have already been diagnosed clinically by various, but varying, professionals. Inappropriate use of classification criteria as diagnostic criteria increases

**TABLE 75-1** Spondyloarthritis

| |
|---|
| Typical pattern of peripheral arthritis—predominantly of lower limb, asymmetric |
| Absence of rheumatoid factor |
| Absence of subcutaneous nodules and other extra-articular features of rheumatoid arthritis |
| Overlapping extra-articular features characteristic of the group (e.g., anterior uveitis) |
| Significant familial aggregation |
| Association with *HLA-B27* |

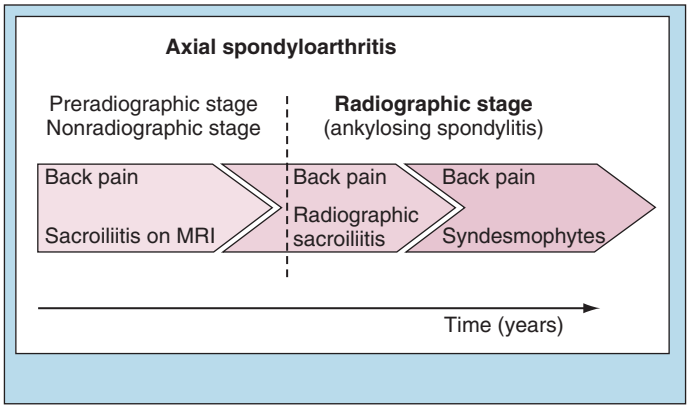

**Figure 75-1** Concept of axial spondyloarthritis as an umbrella for patients without radiographic damage and patients with such damage. MRI, Magnetic resonance imaging.

**TABLE 75-3** Criteria for Ankylosing Spondylitis

| |
|---|
| **Rome, 1961** |
| Clinical Criteria |
| 1. Low back pain and stiffness for more than 3 months not relieved by rest |
| 2. Pain and stiffness in thoracic region |
| 3. Limited motion in lumbar spine |
| 4. Limited chest expansion |
| 5. History or evidence of iritis or its sequelae |
| Radiographic Criterion |
| Radiograph showing bilateral sacroiliac changes characteristic of ankylosing spondylitis (this excludes bilateral osteoarthritis of sacroiliac joints) |
| Definite Ankylosing Spondylitis |
| Grade 3 or 4 bilateral sacroiliitis with at least one clinical criterion |
| or |
| At least four clinical criteria |
| **Modified New York, 1984** |
| Criteria |
| 1. Low back pain of at least 3 months' duration improved by exercise and not relieved by rest |
| 2. Limitation of lumbar spine in sagittal and frontal planes |
| 3. Chest expansion decreased relative to normal values for age and sex |
| 4. Bilateral sacroiliitis grade 2 to 4 |
| 5. Unilateral sacroiliitis grade 3 or 4 |
| Definite Ankylosing Spondylitis |
| Unilateral grade 3 or 4, or bilateral grade 2 to 4 sacroiliitis and any clinical criterion |
| Grading of Radiographs |
| Normal, 0; suspicious, 1; minimal sacroiliitis, 2; moderate sacroiliitis, 3; ankylosis, 4 |

Data from van der Linden SM, Valkenburg HA, Cats A: Evaluation of diagnostic criteria for ankylosing spondylitis: a proposal for modification of the New York criteria. *Arthritis Rheum* 27:361–368, 1984.

the likelihood of false-positive diagnoses, especially in settings in which the prior probability of the disease is low.

The diagnosis of AS is based on clinical features. The disease is "primary" or "idiopathic" if no associated disorder is present, and it is "secondary" if the disease is associated with psoriasis or chronic inflammatory bowel disease. In daily practice, a presumptive clinical diagnosis of AS is usually supported by evidence of sacroiliitis on conventional pelvic radiographs. Although radiographic sacroiliitis is frequent in AS, it is by no means an early or obligate manifestation of the disease.[13] Contrary to the New York criteria, radiographic evidence of sacroiliitis is not obligatory to fulfill the Rome criteria (Table 75-3). Both the Rome and New York criteria were primarily intended for use in epidemiologic studies. Lack of either sensitivity or specificity led to a modification of the New York criteria for AS[5] (see Table 75-3). Two criteria: limitation of lumbar spine motion and limitation of chest expansion, appear to reflect disease duration. They are usually not present in early disease.[14] Therefore the modified New York criteria are not useful for inclusion of early cases of AS because of a lack of sensitivity. MRI is useful to detect axial manifestations before the presence of radiographic sacroiliitis.[15] To encompass both nonradiographic AS and classic AS (according to the modified New York criteria), classification criteria have been proposed for the full spectrum of AS (Table 75-4).[11] The term *axial spondyloarthritis* provides an umbrella for the entire spectrum of patients with predominant axial involvement, regardless of the presence of structural damage on radiographs. Thus axial spondyloarthritis includes nr-axSpA and classic AS (fulfilling the modified New York criteria). According to the Assessment of SpondyloArthritis (ASAS) classification criteria,[11] a patient with chronic back pain and age at onset younger than 45 years can be classified (but not diagnosed) with axSpA if sacroiliitis on imaging (radiographs or MRI) is present, plus at least one other spondyloarthritic (SpA) feature, or, in the absence of sacroiliitis on imaging, if *HLA-B27* plus at least two further SpA features are present (see Table 75-4). The sensitivity of the entire set of ASAS criteria for axSpA was 83%, and the specificity was rather low (84%).[11] In the ASAS study on these new criteria, 30% of all patients considered to have axSpA had definite radiographic sacroiliitis and fulfilled the modified New York criteria for AS. Therefore two-thirds were classified with nr-axSpA.[11] It should be noted that patients classified with axSpA according to the ASAS criteria, tend to be more heterogenous than AS patients classified by modified New York criteria.[11,12,15a]

**TABLE 75-4** ASAS Classification Criteria for Axial Spondyloarthritis in Patients with Back Pain 3 Months or More and Age at Onset Younger Than 45 Years

| Sacroiliitis on Imaging plus ≥1 SpA Feature | OR | *HLA-B27* plus ≥2 Other SpA Features |
|---|---|---|

| SpA Features | Sacroiliitis on Imaging |
|---|---|
| Inflammatory back pain<br>Arthritis<br>Enthesitis (heel)<br>Uveitis<br>Dactylitis<br>Psoriasis<br>Crohn's disease/ulcerative colitis<br>Good response to NSAIDs<br>Family history for SpA<br>*HLA-B27*<br>Elevated CRP* | Active (acute) inflammation on MRI highly suggestive of sacroiliitis associated with SpA<br>OR<br>Definite radiographic sacroiliitis according to modified New York criteria |

*Elevated CRP is considered a SpA feature in the context of chronic back pain.

ASAS, Assessment of Spondyloarthritis International Society; CRP, C-reactive protein; HLA-B27, human leukocyte antigen-B27; IBP, inflammatory back pain; MRI, magnetic resonance imaging; NSAIDs, nonsteroidal anti-inflammatory drugs; SpA, axial spondyloarthritis.

From Rudwaleit M: New classification criteria for spondyloarthritis. *Int J Adv Rheumatol* 8:1–7, 2010.

The full spectrum of AS includes patients defined by the modified New York criteria as well as patients with nr-axSpA by ASAS classification criteria. However, fulfilling the ASAS criteria does not guarantee AS. Inappropriate use of the ASAS criteria as diagnostic criteria for individual patients may cause incorrect labeling as axial spondylitis due to insufficient specificity of the criteria in diagnostic settings.[15a]

## EPIDEMIOLOGY

### Prevalence

The prevalence of AS closely parallels the frequency of *HLA-B27*. This holds true for those B27 subtypes that are associated with the disease, but it is not true for populations in which the *HLA-B27*06* subtype, which lacks a strong association with AS, occurs frequently.[16-18]

Among whites, the estimated prevalence rate of AS, as defined by the modified New York criteria, ranges from 68 per 100,000 in a population older than 20 years in The Netherlands, to 197 per 100,000 in the United States.[19,20] In the general population, AS is likely to develop in approximately 1% to 2% of *HLA-B27*$^+$ adults who have a disease-associated B27 subtype, although there may be regional or geographic differences.[19,21] For example, in northern Norway, AS may develop in 6.7% of *HLA-B27*$^+$ people.[21]

The disease is much more common among *HLA-B27*$^+$ first-degree relatives of *HLA-B27*$^+$ AS patients; roughly 10% to 30% of them have signs or symptoms of AS.[19] In fact, a positive family history of AS is a strong risk factor for the disease.

### Incidence

There is no adequate evidence that the incidence of AS has changed in the past few decades.[22] Clinical features, age of onset, and survival time have remained stable.[23] This study revealed an overall age and gender-adjusted incidence of 7.3 per 100,000 person-years.

### Racial Distribution

AS occurs in all parts of the world, but there are race-related differences in prevalence. This might reflect differences in the distribution of *HLA-B27* among races. Approximately 90% of white patients with AS possess *HLA-B27*, whereas AS and *HLA-B27* are nearly absent (prevalence of B27 <1%) in African blacks and Japanese. In African-Americans, because of racial admixture with whites, 2% possess B27, but only approximately 50% of black patients with AS possess B27. Correspondingly, African-Americans are affected far less frequently than American whites.

### Burden of Disease

AS is associated with a considerable burden to the patient and society. Apart from axial and articular manifestations, extra-articular manifestations, such as enthesitis and acute anterior uveitis, and comorbidities, such as inflammatory bowel disease and psoriasis, contribute to the burden of disease. In addition, a large proportion of patients has spinal osteoporosis, leading to vertebral fractures and thoracic kyphosis. All of these features result in a decreased quality of life. Disease status scores for physical functioning and disease activity correlate clearly with psychological scores for anxiety and depression.[24] The impact of AS can also be seen in various aspects of employment, ranging from required assistance at work to increased sick leave and withdrawal from the workforce.[25,26] AS patients have an important impact on health care and non–health care resource utilization, resulting in mean total costs (direct and productivity) of approximately $6,700 to $9,500 per year per patient.[27-29]

The burden of illness increases with duration of disease. Because the burden caused by AS reduces quality of life, and because all types of costs associated with AS result from loss of function and disease activity, early diagnosis and treatment are necessary to prevent or reduce functional decline and improve patient outcome.[30]

## GENETICS

Twin and family studies have shown that the risk for AS runs strongly in families and is largely genetically determined, and that genetic factors also play major roles in determining disease activity and severity.[31,32] Major progress has been made in recent years in defining the alleles (genetic variants) that underlie this genetic predisposition, with 41 known loci (genetic regions) associated with the disease, including different loci within the major histocompatibility complex (MHC), and in non-MHC regions.

### Major Histocompatibility Complex Associations with Ankylosing Spondylitis

The association of *HLA-B27* with AS was first reported in the early 1970s, and since then increasing numbers of HLA-B27 subtypes have been identified, with more than

100 subtypes now known. The majority of these subtypes are too rare for us to know whether they are disease associated. The ancestral HLA-B27 subtype is *HLA-B*2705*, from which the other subtypes have arisen largely by point mutation. AS has been reported to occur with the following HLA-B27 subtypes: *B*2702*, *B*2703*, *B*2704*, *B*2705*, *B*2706*, *B*2707*, *B*2708*, *B*2710*, *B*2714*, *B*2715*, and *B*2719*. Two subtypes appear to show reduced or possibly absent association with AS; *HLA-B*2706*, which is found in Southeast Asia, and *HLA-B*2709*, which is found in Sardinia. The impact of subtype variation on AS risk has been a cornerstone of research into the mechanism by which HLA-B27 induces AS. HLA-B27 is found in 85% to 95% of cases of primary AS compared with a prevalence in most populations of European descent of approximately 8%.[33] A lower prevalence of HLA-B27 (~60%) is found in AS associated with psoriasis or inflammatory bowel disease.

*HLA-B27* homozygotes have roughly double the risk of AS, compared with B27 heterozygotes. The odds ratio for AS for *HLA-B27* (as defined by the tag single nucleotide polymorphism [SNP] rs116488202) for *HLA-B27* heterozygotes is 62 and for homozygotes 105.[34] *HLA-B27* is widely used in clinical practice as a diagnostic aid in chronic back pain patients; indeed, the clinical arm of the ASAS axSpA classification criteria requires the presence of *HLA-B27* to classify the condition. *HLA-B27* typing is also of use in determining the risk of recurrence of AS in families, with the risk of recurrence extremely low in the absence of *HLA-B27* (<1% chance). Because the prevalence of AS is quite low in the community, and because only approximately 5% of *HLA-B27* cases develop AS, population screening that uses HLA-B27 is not recommended. Disease develops in *HLA-B27*$^-$ individuals on average a decade later than *HLA*-B27$^+$ individuals, but their disease activity and severity of ankylosis is not different. There is some evidence to suggest that *HLA-B27*$^-$ individuals have lower responses to TNF inhibitors; nonetheless, these agents are clearly effective overall in treating *HLA-B27*$^-$ AS. Whether other genetic effects influence responses to TNF inhibitors is unknown in AS, but given that large studies in rheumatoid arthritis have failed to show any convincing evidence of a genetic association with response to TNF inhibitor treatment in that disease, it is unlikely that such an effect will be seen in AS. It will be particularly interesting, however, to see whether genetic variants influence the risk of development of antibodies against TNF inhibitors, which are associated with loss of effectiveness to these agents.

The prevalence of AS worldwide roughly matches the prevalence of HLA-B27. Regions with high *HLA-B27* prevalence include Scandinavia and some North America indigenous populations, and low prevalence is found through most of Africa and in Australian Aboriginals. This variation may be the result of population bottlenecks in human history or natural selection for HLA-B27 in some populations. It should be noted that *HLA-B27* is protective for HIV infection. It has recently been suggested that *HLA-B27* may influence survival, potentially through an effect on cardiovascular risk. This finding suggests another potential selective pressure on *HLA-B27* prevalence.[35]

*HLA-B27* is not the only HLA-B allele associated with AS. Multiple studies confirm a role for *HLA-B60* (also known as *HLA-B40*), which further increases AS risk by approximately 1.5-fold, and it is likely that other *HLA-B* alleles also contribute to the risk.[36] Controlling for association at HLA-B, association is also evident with *HLA-A*0201*.[34] There is suggestive evidence for the association of class III HLA genes, including *MICA* alleles with AS, which, if confirmed, would be consistent for a role of natural killer (NK) cells with the disease.[37] It is likely that other MHC genes are also associated with AS. Distinguishing true positive associations from linkage disequilibrium with the known associations, in particular *HLA-B27*, is extremely challenging because of the complex and extensive linkage disequilibrium that occurs in this region.

## Non–Major Histocompatibility Complex Associations of Ankylosing Spondylitis

The majority of the genetic risk for AS is thought to be determined by loci outside the MHC. To date 40 non-MHC loci have been convincingly demonstrated to be associated with the disease, and these have cast new light on the disease pathogenesis (summarized in Table 75-5).

## Aminopeptidase Genes and Ankylosing Spondylitis

Three genes in the aminopeptidase pathway are robustly associated with AS: *ERAP1* and *ERAP2* encoded at chromosome 5q15 and *NPEPPS* (puromycin-sensitive aminopeptidase) at chromosome 17q21. At least two associated haplotypes are present at *ERAP1*, with one driven by the

*Heritability explained assumes an additive model, disease prevalence 0.5%. Allele frequency and odds ratio are as reported for samples of European ancestry from Cortes et al, and for *ANTXR2* from Karaderi et al.

IL, Interleukin; HLA, human leukocyte antigen; SNP, single nucleotide polymorphism; TCR, T cell receptor; TNF, tumor necrosis factor.

From Cortes A, Hadler J, Pointon JP, et al: Identification of multiple risk variants for ankylosing spondylitis through high-density genotyping of immune-related loci. *Nat Gen* 45:730–738, 2013; and Karaderi T, Keidel SM, Pointon JJ, et al: Ankylosing spondylitis is associated with the anthrax toxin receptor 2 gene *(ANTXR2). Ann Rheum Dis* 73:2054–2058, 2014.

noncoding SNP rs30187, and the second haplotype less well defined, and tagged by the SNP rs10050860.[34] At *ERAP2* the genetic association is very broad, but on the key disease-associated haplotype, one protective variant (rs2248374[G]) leads to a transcribed RNA product that undergoes nonsense-mediated decay and thus no translated protein product.[38] This variant is thus the major functional variant at *ERAP2*.

Gene-gene interaction between *ERAP1* and *HLA-B27* is the first example of replicated, statistically significant interaction in any human disease and indicates that the mechanism by which HLA-B27 induces AS must involve aberrant peptide processing.[39] It is now known that the same variants in *ERAP1* are associated with psoriasis, and interaction is observed with *HLA-Cw6*, the major psoriasis class I HLA allele.[40] Similarly, in Behçet's disease, there is *ERAP1* association restricted to *HLA-B51* cases, the major Behçet's disease class I HLA allele.[41] This suggests that *HLA-B27*, *HLA-Cw6*, and *HLA-B51* operate in these diseases through similar mechanisms.

### Interleukin-23 Pathway Genes and Ankylosing Spondylitis

The genetic discovery of the association of *IL23R* with AS was the first demonstration of the involvement of this pathway in AS and has driven the repositioning of inhibitors of the IL-23 pathway for use in AS. There are now multiple polymorphisms identified with independent associations at *IL23R* that are associated with AS, inflammatory bowel disease (IBD), psoriasis, and other associated diseases. Several other IL-23 pathway genes have also now been associated with AS, including *IL12B*, *TYK2*, and *JAK2*, as well as other genes that interact with the IL-23 pathway such as *IL1RL1*, *IL1RL2*, *IL6R*, *PTGER4*, and *CARD9*. The molecular mechanisms underlying these associations largely await dissection, but these findings clearly demonstrate that this is a major pathway in AS pathogenesis. Consequently, it is a major target for development of therapies for AS. The association of *IL23R* is found in both *HLA-B27*$^+$ and *HLA-B27*$^-$ disease, and thus the pathway is relevant to both AS subsets.[42] Whether these genes play any role in controlling disease activity, severity of ankylosis, or clinical subsets of AS such as those that develop anterior uveitis, is the subject of ongoing research.

### Lymphocyte Development and Activation Genes

The association of AS with multiple cytokines, cytokine receptors, and transcription factors involved in controlling lymphocyte development and activation points to the key involvement of the affected cell types in AS pathogenesis. Associated genes include *EOMES*, *RUNX3*, *TBX21*, *ZMIZ1*, *IL7*, and *IL7R*.[34,42,43] The functional significance of these findings is discussed in more detail in subsequent text.

## PATHOGENESIS

Better understanding of the genetics of AS has advanced understanding of AS pathogenesis. Of the 41 loci associated with susceptibility to developing AS to date several fall into pathogenic "pathways" that may be important immunopathogenic drivers of AS: classic and nonclassic roles of HLA-B27; ERAP1 and other aminopeptidases involved in peptide trimming and antigen presentation; IL-23 and IL-17 cytokines.[34]

### HLA-B27

Despite more than 40 years of research, the precise role of HLA-B27 in AS remains unclear. Current models for how HLA-B27 operates in AS can be divided into classic models of how class I alleles operate in antigen presentation versus nonclassic models associated with irregular properties of HLA-B27, including slow folding rate and cell-surface homodimer formation.

The dominant role of class I HLA molecules, such as HLA-B27, is in presentation of antigens to CD8 T lymphocytes. In the case of infected or transformed cells, presentation of foreign or tumor antigens provide danger signals to CD8 lymphocytes. The "arthritogenic peptide" model of AS pathogenesis suggests that in genetically predisposed individuals, aberrant presentation of self-peptides by HLA molecules results in recognition of innocuous self-antigens as harmful, inducing autoreactivity from CD8 T cell responses. Self-reactive T cells have been isolated from synovium of AS patients,[2] but these studies have not been convincingly replicated.[44-46] This model is not well supported by studies in B27-transgenic rats, in which disease pathogenesis is independent of CD8 T cells. One caveat to this model is that B27-transgenic rats express in the region of 40 to 50 copies of HLA-B27 per cell compared with, at most, two copies in humans. The effects of such overexpression of class I alleles in this animal model require cautious interpretation of data from such experiments because it is possible that an AS-like condition may arise from different pathogenic mechanisms.

During antigen processing and presentation, the highly polymorphic heavy chain of HLA-B27 noncovalently associates with β2-microglobulin, and that complex is loaded with a peptide before transport of this complex to the cell surface. The highly ordered process of HLA:peptide assembly, which occurs in the endoplasmic reticulum (ER), happens more slowly for HLA-B27 than any other HLA molecule.[47] The unfolded protein response (UPR) theory suggests that slow assembly of HLA-B27 complexes initiates endoplasmic reticulum stress pathways that lead to the secretion from macrophages of IL-23. Support for the UPR theory is, again, strongest in B27-transgenic rats but has also been reported in the synovium of AS patients.[48,49] However, recent data from AS patients have found little evidence for ER stress in circulating cells in AS patients.[50]

Following transport to the cell surface, β2-microglobulin can dissociate from the heavy chain, leaving a free heavy chain. Free heavy chains can then dimerize to form cell surface heavy-chain homodimers. Recent reports have shown that subsets of T cells and NK cells can recognize the B27 homodimers through specific killer immunoglobulin receptors (KIRs). Recognition of cell surface B27 heavy-chain homodimers by KIR3DL2$^+$ CD4 T cells leads to IL-17 secretion by those T cells.[51]

## ERAP1 and Other Aminopeptidases

Outside the *HLA* locus, *ERAP1* is the strongest association with AS susceptibility. ERAP1 is an aminopeptidase involved in trimming of peptides that have been processed through the proteasome from approximately 13 to 15 amino acids in length down to 8 to 9 amino acid peptides. ERAP1 is therefore considered to be a "molecular ruler," shaping peptides before loading onto class I MHC molecules. The association with AS has been described and validated in several studies.[39,52] At least two AS-associated *ERAP1* haplotypes have been described, tagged by the nonsynonymous SNPs rs30187 and rs10050860.[34] These SNPs only show association with HLA-B27$^+$ patients, thus demonstrating gene-gene interaction between *ERAP1* and *HLA-B27*.[39] Despite this new knowledge, our understanding of the precise role of ERAP1 in AS pathogenesis remains limited.

ERAP1 exists in either a closed (enzymatically active) or open (enzymatically inactive) state. X-ray crystallography revealed that the main AS-associated SNP rs30187 (K528R) in *ERAP1* is located at the hinge region of the enzyme that controls the switch between open and closed conformations, and studies using recombinant ERAP1 and in cell lines have shown that this variant is associated with reduced ERAP1 function.[39,53]

*ERAP1* polymorphisms could contribute to all three models for how HLA-B27 operates in AS. Altered rates of peptide trimming mediated by ERAP1 could lead to cell surface presentation of aberrant peptides in the context of HLA-B27. Altered enzyme activity could affect the rate at which HLA-B27:peptide complexes fold within the ER, thereby contributing to the UPR and ER stress. Recently, ERAP1 variants have been reported to alter levels of HLA-B27 cell surface free heavy chains.[54]

Controlling for the association of *EPAP1*, variants in two additional aminopeptidases falling within the chromosome 5q15 locus, *ERAP2* and leucyl/cystinyl aminopeptidase *(LNPEP)*, have also been identified.[34] Association with the lead SNP in *ERAP2* remains significant in HLA-B27$^-$ cases; whether *LNPEP* is independently associated with AS is unclear. The cytosolic aminopeptidase *NPEPPS* at chromosome 17q21 is the fourth aminopeptidase demonstrating an association with disease, involved in peptide processing prior to transport of substrates into the ER.[34] As with *ERAP1*, loss-of-function variants in *ERAP2* are protective against AS. The protective allele at rs2248374 produces truncated *ERAP2* transcripts that undergo nonsense-mediated decay, knocking down expression of the protein completely in homozygote individuals and by approximately 50% in heterozygotes.[38] Further understanding of how each of these aminopeptidases functions in AS is warranted, but inhibition of ERAP1 and ERAP2, at least, appears as an attractive therapeutic strategy for AS.

## IL-23 Signaling Pathway

IL-23 signals through a cell surface receptor composed of an IL-23–specific subunit (IL-23R) and a subunit shared with IL-12R (IL-12RB1). IL-23 signaling is necessary for the development of IL-17– and IL-22–secreting cells. As described previously, polymorphisms in *IL23R* and, more recently, downstream components of the IL-23 signaling pathway, *JAK2* and *Tyk2*, and the IL-23 subunit *IL12B*, have been associated with AS.[34,52]

Under normal physiologic conditions, IL-23, IL-17, and IL-22 regulate gut homeostasis. IL-23, IL-23R, and IL-17 are increased in AS. Inhibition of either IL-12/IL-23 or IL-17 with monoclonal antibodies ustekinumab or secukinumab, respectively, are promising new therapeutics in AS, displaying similar efficacy to TNF antagonists.

Improved understanding of the cells involved in IL-23 signaling in AS has shone light on new immune cell subsets involved in AS pathogenesis. Until recently, CD4 T cells were thought to be the dominant cell type involved in IL-23–mediated immune responses. However, studies in IL-23R–green fluorescent protein (GFP) reporter mice revealed that CD4 T cells are only a small component of the IL-23 signaling family. Several other cell types in these mice express high levels of IL-23R, including γδ T cells, macrophages, dendritic cells, and lymphoid tissue inducer-like (LTi) cells. In AS patients, several "noncanonical" IL-23–responsive cells have been described, including γδ T cells, KIR3DL2$^+$ CD4 T cells, mast cells and neutrophils.[51,55-57] The precise hierarchy of these cell types remains unclear, but it is conceivable that each cell type may play tissue-specific roles in regulating IL-23 responses in AS. The prominent source of IL-23 in AS also remains unclear.

# STRUCTURAL REMODELING AND ANKYLOSIS

A major distinguishing feature of seronegative from seropositive arthropathies is that although, at least early in both groups of diseases, inflammation typically causes erosion; in later stages, seronegative disease osteoproliferation occurs. There is little direct evidence in humans about the processes involved in osteoproliferative disease because of the difficulty in obtaining suitable specimens for histopathologic examination. Therefore most of the information that is available comes from imaging studies or from studies of murine models of disease.

Inflammation is clearly a critical early step in the osteoproliferative process. Baseline C-reactive protein (CRP) is a predictor of future radiographic change, and there is increasing evidence that although TNF inhibition does not altogether prevent bone formation, it does significantly slow ankylosis.[58] It had been postulated that TNF inhibition released Wnt-pathway–driven bone formation due to reduction in expression of the Wnt inhibitor DKK1.[59] However, this would be expected to lead to accelerated ankylosis in TNF inhibitor–treated patients, when in fact the converse appears to be the case.

Similarly, chronic nonsteroidal anti-inflammatory drug (NSAID) use, particularly in patients with elevated acute phase reactants, also slows ankylosis, albeit marginally.[60] This may relate to the known association of AS with genetic variants in *PTGER4*,[39] which encodes a receptor for prostaglandin $E_2$; $PGE_2$ is produced at entheses in response to physical stress, driving IL-23 production and bone formation.

MRI studies suggest that bone marrow fat metaplasia is an intermediate step prior to new bone formation, and that once fat metaplasia has occurred, new bone formation may

develop. The cell and molecular processes that are involved are not well understood, but animal model studies suggest involvement of the Wnt and BMP pathways, which are the major bone anabolic pathways in bony animals.[61] These may prove useful targets for reducing the rate of ankylosis in AS, but medications that specifically target inflammation-induced bone formation will be required to avoid generalized osteoporosis as a therapeutic side effect.

Recently noggin (NOG) and sclerostin (SOST) have been associated with the disease, and they might contribute to neoossification in AS patients.[62]

Currently, it remains unclear whether early suppression of inflammation leads to a decrease of the risk of new bone formation in AS.[63]

## CLINICAL MANIFESTATIONS

### Skeletal Manifestations

#### Low Back Pain and Stiffness

Back pain is an extremely common symptom, occurring in as much as 80% of the general population. Therefore it is important to note that back pain in AS and axSpA has special features that differentiate it from mechanical back pain[64-66] (Table 75-6). In clinical practice, inflammatory back pain is often not well recognized.[67] Back pain is the most prevailing diagnostic feature of AS (Table 75-7).

The pain is initially felt primarily deep in the gluteal region, is dull in character, is difficult to localize, and is insidious in onset. The pain can be severe at this early phase of the disease; it localizes in the SI joints but is occasionally referred toward the iliac crest or greater trochanteric region or down the dorsal thigh. Radiation of buttock pain may suggest root compression of the sciatic nerve. The buttock pain typically alternates from side to side. Coughing, sneezing, or other maneuvers that cause a sudden twist of the back may accentuate pain. Although the pain is often unilateral or intermittent at first, within a few months, it usually becomes persistent and bilateral, and the lower lumbar area becomes stiff and painful. The pain is associated with a feeling of low back stiffness that is worse in the morning and may awaken the patient from sleep, particularly during the second half of the night. Many patients do not differentiate between low back pain and stiffness. The morning stiffness may last as long as 3 hours. Both the stiffness and the pain tend to be eased by a hot shower, an exercise program, or physical activity; they do not improve with rest. Fatigue as a result of chronic back pain and stiffness may be an important problem and can be accentuated by sleep disturbances due to these symptoms.

**TABLE 75-6** Aspects of Inflammatory Back Pain in Ankylosing Spondylitis and Axial Spondyloarthritis

| |
|---|
| Onset of complaints before age 45 years |
| Duration of symptoms more than 3 mo (chronic pain) |
| Located at the lower back |

#### Chest Pain

With subsequent involvement of the thoracic spine (including costovertebral and costotransverse joints) and the occurrence of enthesitis at the costosternal and manubriosternal joints, patients may experience chest pain accentuated by coughing or sneezing, which is sometimes characterized as "pleuritic." The chest pain is often associated with tenderness over the costosternal junctions. Mild to moderate reduction of chest expansion may be detectable in an early stage of AS. Chest pain occurs relatively often in *HLA-B27*$^+$ relatives, even in the absence of radiographic evidence of sacroiliitis.[68]

#### Tenderness

Extra-articular tenderness at certain loci is a prominent complaint in some patients. These lesions are caused by enthesitis. Common tender sites are the costosternal junctions, spinous processes, iliac crests, greater trochanters, ischial tuberosities, tibial tubercles, and heels (Achilles tendinitis or plantar fasciitis). Radiographically, bone spurs may develop at these sites.

#### Joints

The girdle or "root" joints (hips and shoulders) are the most frequently involved extra-axial joints in AS, and pain in these areas is the presenting symptom in as many as 15% of patients. Shoulder involvement, but especially hip involvement, may cause considerable physical disability. Coexisting disease in the lumbar spine often contributes significantly to disability of the lower extremities. Hips and shoulders are involved at some stage of disease in as many as 35% of patients. Hip disease is relatively more common as a presenting manifestation if the disease starts in childhood (juvenile AS). In boys 8 to 10 years of age, hip disease as a manifestation of juvenile AS is the most frequent type of chronic arthritis. These children with hip disease are mostly *HLA-B27*$^+$, and negative for anti-nuclear antibodies.

The knee joint may also be affected in AS, often as an intermittent effusion. The temporomandibular joint is involved in approximately 10% of patients.

## Extraskeletal Manifestations

Constitutional symptoms such as fatigue, weight loss, and low-grade fever occur frequently. Other extraskeletal manifestations are more localized.

### Eye Disease

Acute anterior uveitis or iridocyclitis is the most common extra-articular manifestation of AS, occurring in 25% to 30% of patients at some time during the course of the disease. There is no clear relationship between activity of the articular disease and this extra-articular manifestation. The onset of eye inflammation is usually acute and typically unilateral, but the attacks may alternate. The eye is red and painful, with visual impairment. Photophobia and increased lacrimation may be present. If the eye remains untreated or if treatment is delayed, posterior synechiae and glaucoma may develop. Most attacks subside in 4 to 8 weeks without sequelae if early treatment is provided. Acute anterior uveitis is more common in $B27^+$ than $B27^-$ patients with AS.[69] Relatives who have acute anterior uveitis seem to be at higher risk for AS. The calculated incidence of acute anterior uveitis in a Swiss family study was 89 attacks per 1000 patient-years for AS patients, but only 8 attacks per 1000 person-years among healthy $B27^+$ relatives.[70]

### Cardiovascular Disease

Cardiac involvement may be clinically silent or may cause considerable problems. Manifestations of cardiac involvement include ascending aortitis, aortic valve incompetence, conduction abnormalities, cardiomegaly, and pericarditis. In rare situations, aortitis may precede other features of AS. Aortic incompetence was noted in 3.5% of patients who had the disease for 15 years and in 10% after 30 years.[71] Inflammation and dilation of the aorta are the main causes of aortic valve incompetence. Cardiac conduction disturbances are seen with increasing frequency with the passage of time, occurring in 2.7% of those with disease of 15 years' duration and in 8.5% after 30 years.[71] Both aortic incompetence and cardiac conduction defects occur twice as often in patients with peripheral joint involvement. In AS the prevalence of myocardial infarction is increased (4.4%) in AS patients compared with 1.2% in the general population.[72]

### Pulmonary Disease

Lung involvement is a rare and late manifestation of AS. It is characterized by slowly progressive fibrosis of the upper lobes of the lungs, appearing, on average, 2 decades after the onset of AS. Patients may complain of cough, dyspnea, and sometimes hemoptysis.[73]

High-resolution computed tomography (CT) may be helpful in detecting interstitial lung disease in patients with respiratory symptoms whose chest radiographs are normal.[74,75]

Pulmonary ventilation is usually well maintained; an increased diaphragmatic contribution helps compensate for chest wall rigidity, which is due to involvement of the thoracic joints in the inflammatory process. Vital capacity and total lung capacity may be moderately reduced as a consequence of the restricted chest wall movement, whereas residual volume and functional residual capacity are usually increased.

### Neurologic Involvement

Neurologic complications of AS can be caused by vertebral fracture, instability, compression, or inflammation. Traffic accidents or minor trauma can cause fractures of a vulnerable osteoporotic spine.[76] The C5-C6 or C6-C7 level is the most commonly involved site.

As in RA, atlantoaxial joint subluxation, atlantooccipital subluxation, and upward subluxation of the axis may occur in AS as a consequence of instability resulting from the inflammatory process. Spontaneous anterior atlantoaxial subluxation is a well-recognized complication in approximately 2% of patients and manifests with or without signs of spinal cord compression.[77]

Nontraumatic causes of neurologic complications caused by compression include ossification of the posterior longitudinal ligament (which may lead to compressive myelopathy), destructive intervertebral disk lesions, and spinal stenosis.

The cauda equina syndrome is a rare but serious complication of long-term AS. The syndrome affects lumbosacral nerve roots. This gives rise to pain and sensory loss, but frequently there are also urinary and bowel symptoms. Gradual onset of urinary and fecal incontinence, impotence, saddle anesthesia, and occasionally loss of ankle jerks occurs. Motor symptoms, if present, are usually mild. CT and MRI allow the accurate noninvasive diagnosis of this complication of AS.[78] Arachnoiditis and arachnoid adhesions may be important in the pathogenesis.

### Renal Involvement

Renal complications may be elevated among patients with AS.[79] Immunoglobulin (Ig)A nephropathy has been reported in many patients with AS. These patients often have an elevated IgA level (93%) and renal impairment (27%) at presentation.[80] Microscopic hematuria and proteinuria may occur in as many as 35% of patients. The significance of these findings in terms of subsequent deterioration of renal function is unclear.[81] Amyloidosis (secondary type) is a rare complication.[82]

### Osteoporosis

Osteopenia is seen in the early stages of AS.[83] In patients with this disease, osteoporotic deformities of the thoracic spine contribute significantly to abnormal posture, particularly fixed hyperkyphosis.[84] Radiographic damage to the cervical and lumbar spine, thoracic wedging, and disease activity are determinants of hyperkyphosis in AS.[85] An increased occiput-to-wall distance is associated with vertebral fractures. The prevalence of symptomatic osteoporotic spinal fractures is increased in AS.[86] Neurologic

complications occur rather frequently, even after minor trauma.[87] Proper assessment of bone density in the spine is difficult in the presence of syndesmophytes because they may give rise to falsely high values.

## PHYSICAL EXAMINATION

### Spinal Mobility

To arrive at an early diagnosis, the physician must perform a thorough physical examination. On examination of the spine, there may be some limitation of motion of the lumbar spine as elicited by forward flexion, hyperextension, or lateral flexion. Early loss of the normal lumbar lordosis is often the first sign and is easily assessed on inspection.

The Schober test (or its modifications) is useful to detect any limitation of forward flexion of the lumbar spine, although it is typically normal in early disease. While the patient stands erect, one mark is placed with a pen on the skin overlying the fifth lumbar spinous process (usually at the level of the posterosuperior iliac spine or the "dimple of Venus"), and another mark is placed 10 cm above in the midline. The patient is then asked to bend forward maximally, without bending the knees. If the distance between both marks is less than 15 cm, this indicates reduced lumbar spine mobility. Lateral flexion may also be diminished, and spinal rotation may cause pain.

### Chest Expansion

Mild to moderate reduction of chest expansion is often detectable in early stages of AS. Normal values are age and sex dependent, and there is considerable overlap between normal values and those obtained from AS patients. Reduction below 5 cm in young persons with an insidious onset of chronic, inflammatory low back pain strongly suggests AS. Chest expansion should be measured on maximal inspiration after forced maximal expiration at the level of the fourth intercostal space in males and just below the breasts at the xiphisternal level in females.

### Enthesitis

Examination of the ischial tuberosities, greater trochanters, spinous processes, costochondral and manubriosternal junctions, supraspinatus insertion, and iliac crests can determine the presence of enthesitis. Heel pain, especially when getting out of bed, is a characteristic manifestation of Achilles tendon enthesitis and plantar fasciitis.

### Sacroiliitis

Direct pressure over the SI joints may elicit pain, as may special testing maneuvers, although the latter lack specificity and sensitivity. These signs may also be negative in early disease or may become negative in late stages as inflammation is replaced by fibrosis or bony ankylosis.

### Posture

Over the course of the disease, the patient may lose normal posture. Involvement of the cervical spine is manifested by pain and limitation of neck movement. The physician can detect a forward slope of the neck by having the patient stand against a wall and try to position his or her occiput against it.

After many years of progression in patients with severe disease, the entire spine may become increasingly stiff, with loss of normal posture from gradual loss of lumbar lordosis and the development of thoracic kyphosis.[84,85] The abdomen becomes protuberant; breathing is primarily by diaphragmatic action. These typical deformities usually evolve after disease duration of 10 years or more.

## LABORATORY TESTS

Generally, routine blood tests are not helpful. A normal erythrocyte sedimentation rate (ESR) or normal CRP level does not exclude active disease. An elevated ESR or CRP is reported in as many as 75% of patients, but it may not correlate with clinical disease activity.[88] Neither ESR nor CRP is superior in assessing disease activity.[89] A mild normochromic anemia may be present in 15% of patients. Elevation of serum alkaline phosphatase (derived primarily from bone) is seen in some patients but is unrelated to disease activity or duration. Some elevation of serum IgA is frequent in AS. Its level correlates with acute phase reactants. Active disease is associated with decreased lipid levels, particularly high-density lipoprotein cholesterol, resulting in a more atherogenic lipid profile.[90]

## IMAGING STUDIES

### Conventional Radiography

The typical radiographic changes of AS are seen primarily in the axial skeleton, especially in the SI, discovertebral, apophyseal, costovertebral, and costotransverse joints. They evolve during many years, with the earliest, most consistent, and most characteristic findings seen in the SI joints. The radiographic findings of sacroiliitis consist of blurring of the subchondral bone plate, followed by erosions and sclerosis of the adjacent bone. The changes in the synovial portion of the joint (i.e., the lower one-third of the joint) primarily result from inflammatory osteitis of the adjacent subchondral bone.[91] Progression of the subchondral bone erosions can lead to pseudowidening of the SI joint space. With time, gradual fibrosis, calcification, interosseous bridging, and bony ankylosis occur. It is practical to grade radiographic sacroiliitis according to the New York criteria (Table 75-8).

Bony erosions and osteitis ("whiskering") at sites of osseous attachment of tendons and ligaments are frequently seen, particularly at the calcaneus, ischial tuberosities, iliac

**TABLE 75-8** Grading of Sacroiliitis: New York Criteria

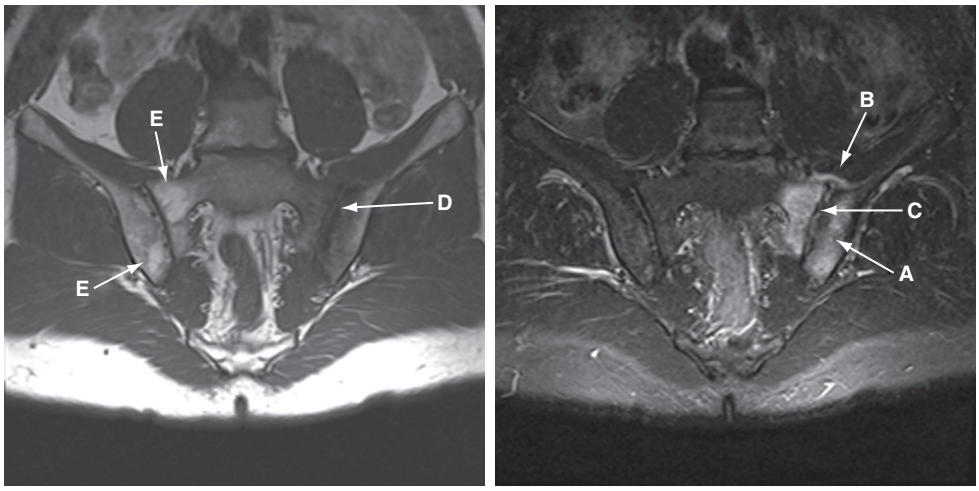

**Figure 75-2** T1-weighted *(left)* and short-tau inversion recovery sequence magnetic resonance *(right)* images of 23-year-old male with inflammatory back pain and equivocal pelvic radiograph demonstrating the following features: *A,* Bone marrow edema in left iliac and sacral bones; *B,* capsular inflammation; *C,* joint space inflammation; *D,* diffuse erosion of left iliac bone with widening of joint space; *E,* fat infiltration in right sacrum and ilium.

crest, femoral trochanters, supraspinatus insertion, and spinous processes of the vertebrae. In the early stages of the evolution of syndesmophytes, there is inflammation of the superficial layers of the annulus fibrosus, which leads to erosion of the adjacent corners of the vertebral bodies visible on radiography. Tissue repair leads to "squaring" of the vertebral bodies and reactive bone sclerosis, which constitute the Romanus lesion seen on radiography. Gradual ossification of the annulus fibrosus may lead to complete bony "bridging" between vertebrae.[92] Concomitant ankylosis often occurs in the apophyseal joints, with ossification of the adjacent ligaments. In a number of patients, this may result in complete fusion of the vertebral column ("bamboo spine").

Hip involvement may lead to concentric joint space narrowing, irregularity of the subchondral bone with subchondral sclerosis, osteophyte formation at the outer margin of the articular surface, and, ultimately, bony ankylosis.

Several validated scoring methods are available to quantify structural damage in AS: the Bath AS Radiology Index (BASRI), the Stoke AS Spondylitis Score (SASSS), and the modified SASSS.[93-95] The BASRI includes scores for the cervical and lumbar spine, as well as the SI and hip joints. The SASSS evaluates the lumbar spine only; the modified SASSS assesses the anterior cervical and lumbar spine. These scoring methods are most suited for use in clinical trials and observational studies.

## Computed Tomography and Magnetic Resonance Imaging

CT may detect bone abnormalities such as sclerosis and erosion sooner than plain radiography, but its use is limited by radiation exposure, and it does not detect changes in soft tissues or bone marrow where early features of sacroiliitis develop. MRI sequences that are used in routine practice to image the SI joint can detect sacroiliitis in at least 50% of patients with nonradiographic SpA.[96] These sequences include fat-saturating techniques, such as short-tau inversion recovery (STIR), that are very sensitive in the detection of bone marrow edema, which is a frequent finding in SpA (Figure 75-2). The T1-weighted (T1W) sequence allows detection of erosions and fat metaplasia, which may occur early in the disease and are associated with resolution of inflammation. Diagnostic MRI should include both sequences, whereas the role of contrast enhancement with gadolinium is still unclear because of its substantial cost and the prolonged time for imaging, which some patients find difficult to endure.

Spinal inflammation can only be visualized by MRI, where it is typically seen as bone marrow edema in the vertebrae at both anterior and posterior vertebral corners, as well as around the intervertebral disk. Lateral and posterior elements, such as the costovertebral and costotransverse joints, facet joints, pedicles, and spinal ligaments, can also show inflammatory lesions.[97] Resolution of inflammation is associated with development of fat metaplasia in these same locations. MRI and ultrasonography can be useful to assess enthesitic problems such as Achilles tendinitis and heel pain. Definitions for the assessment of enthesitis by ultrasound have been established.[98] Quantification of spinal inflammation by using MRI is highly sensitive to change and is now recognized as an essential component of clinical trials. MRI scores for inflammation correlate well with CRP, but only weakly with symptoms in patients with AS. Evidence supports an association between MRI inflammation and the future development of structural changes on radiography.[6,99] Resolution of inflammation, especially with TNF blockers, is associated with the development of fat metaplasia in the sacroiliac joints and the spine.[100,101] The histopathology of this lesion remains unclear, but it may be an important intermediary tissue associated with the development of ankylosis.[102,103] Evidence suggests that inflammatory lesions with no signs of concomitant fat metaplasia may resolve completely without sequelae, provided effective anti-inflammatory therapy is administered.[63,104] On the other hand, inflammatory lesions that already demonstrate fat metaplasia may be at higher risk of developing into new bone formation, even if the inflammation resolves with treatment. Consequently, the concept of a window of opportunity for effective treatment

with anti-inflammatory agents has been proposed and will require further testing in prospective studies.

## DIAGNOSIS

Clinical manifestations of AS usually appear in patients in late adolescence or early adulthood; only rarely do they appear in adults older than 40 years.[19] The diagnosis of AS at an early stage of disease depends primarily on a careful history and physical examination. Two features of the history are critical: (1) the presence of inflammatory low back pain and stiffness, and (2) a positive family history for AS.

Low back pain in AS has typical "inflammatory" features (see Table 75-6). A positive family history increases the pretest probability of AS from 0.1% for a person belonging to the general population to approximately 10% for any first-degree relative of an AS proband.[19] The probability that a first-degree relative with a positive family history of AS will have AS increases from 10% to nearly 50% if this relative has inflammatory low back pain. In contrast, the likelihood that a person who has inflammatory back pain (without any other inflammatory indications listed in Table 75-9) but has a negative family history for AS will have AS increases from 0.1% to only 1%. A definite diagnosis of AS is usually established by radiographic evidence of bilateral sacroiliitis. The plain anteroposterior (AP) view of the pelvis is usually adequate for diagnostic purposes. A major challenge to early diagnosis by using radiography is the complex anatomy of the joint. The cartilaginous portion, which is the region primarily affected in early disease, is convex anteroinferiorly in the anterior one-third of the joint. In addition, the joint cavity is oblique, with the posterior aspect located medially and the anterior located laterally. This creates difficulty in the interpretation of early subchondral changes by using the conventional AP view. Overlying bowel gas and soft tissues further confound detection of abnormalities. Erosion may therefore be quite severe in the SI joint before detection, and this has led to the use of various imaging approaches in clinical practice to optimize radiographic assessment of the SI joint. Reliable detection of radiographic sacroiliitis is difficult, even for experienced readers, and after extensive training and calibration.[105,106]

There is little evidence to support the use of specific SI joint views, such as oblique views or the Ferguson view, versus the conventional AP of the pelvis. Moreover, there is minimal additional diagnostic utility to the use of specific SI joint views in which the AP of the pelvis is equivocal for sacroiliitis, which comes at the expense of additional exposure to radiation. In the setting of suspicion of early AS, in which an AP pelvic radiograph is reported as equivocal, MRI of the pelvis would be a more useful option than additional radiography.

**TABLE 75-9** Proposed Criteria for Inflammatory Back Pain in Young to Middle–Aged Adults* with Chronic Back Pain

| Alternating buttock pain |

*Younger than 50 years.

From Rudwaleit M, Metter A, Listing J, et al: Inflammatory back pain in ankylosing spondylitis: a reassessment of the clinical history for application as classification and diagnostic criteria. *Arthritis Rheum* 65:569–578, 2006.

In most adult patients, AS can be diagnosed clinically without the *HLA-B27* test. This assessment often has no additional value in established disease or as a pure screening tool.[107] However, in young patients with inflammatory chronic back pain, a positive *HLA-B27* test increases the likelihood of having AS, particularly if imaging of the SI joints does not provide conclusive results. In this setting, MRI may help to classify patients with SpA or non-SpA.[96,108]

An approach based on pretest probabilities and likelihood ratios has been proposed to diagnose early disease with predominantly axial manifestations before convincing evidence of radiographic sacroiliitis.[65] The majority of patients diagnosed clinically with nr-axSpA have MRI evidence of SpA,[96] and the severity of bone edema on MRI has been shown to predict the development of radiographic sacroiliitis on follow-up.[6] Consequently, MRI is now an acceptable imaging criterion for the diagnosis of SpA and is especially useful when the history points to inflammatory back pain, the pelvic radiograph is normal or equivocal, and the patient is positive for HLA-B27 or has a positive family history for AS. MRI studies in such settings should include T1W and STIR of the sacroiliac joint. Imaging is conducted in the oblique coronal plane with consecutive slices parallel to the dorsal surface of the sacrum so that the cartilaginous portion of the joint can be adequately visualized. Imaging in the axial plane may provide better visualization of the ligamentous portion, but it has not been shown that this enhances diagnostic utility. Contrast enhancement with gadolinium may be useful in demonstrating lesions such as synovitis and capsulitis, but these often occur concomitantly with subchondral bone marrow edema so that diagnostic utility is not enhanced.[109] Bone marrow edema in subchondral bone is detected by using fat-suppressed sequences such as STIR and is the most frequent lesion in early disease. A definition of a positive MRI has been proposed according to consensus by Assessment for Ankylosing Spondylitis/Outcome Measures in Rheumatology (ASAS/OMERACT), which states that a single coronal slice that clearly demonstrates bone marrow edema in several locations is sufficient to designate a scan as positive for SpA.[110] A single lesion must be evident in two consecutive slices for a scan to be considered positive for SpA. Assignment of a positive MRI by using this definition can be done more reliably than for radiographic sacroiliitis.[111]

Studies with age- and sex-matched controls have shown that false positives may occur in 15% to 20% with use of this definition, and that assessment of structural lesions, especially erosions, may enhance detection of SpA.[96,112] Fat metaplasia may be diagnostically useful when it is observed adjacent to subchondral bone, has a distinct border, and a homogeneous increase in T1W signal. However, it is unusual to see fat metaplasia alone, and it is often observed with other structural lesions as well as bone marrow edema.[113] A key principle for evaluation of MRI scans is the simultaneous evaluation of both T1W and STIR sequences, because each often provides information that enhances confidence

in overall diagnostic ascertainment. For instance, subtle bone marrow edema may by itself not be definitive for SpA, but if the T1W scan also demonstrates an erosion or a region of fat metaplasia, the sum of the MRI evaluation may be definitive for SpA.

Spinal MRI is conducted in the sagittal plane, and the spine is imaged in cervicothoracic and thoracolumbar halves. It may demonstrate vertebral corner bone marrow edema and/or fat metaplasia in nr-axSpA. However, spinal MRI is not recommended for routine evaluation of SpA unless the SI joint scan is equivocal and the clinical index of suspicion for SpA is high. Vertebral corner lesions demonstrating bone marrow edema and/or fat metaplasia may be observed at two to three spinal levels in healthy individuals, especially in patients with mechanical disorders.[114] Conventional spinal imaging does not extend sufficiently laterally to cover all lateral spinal structures that could be inflamed. Specific MRI protocols for spinal imaging in axSpA have been developed to address this potential shortcoming.[97]

At the other end of the age scale, juvenile-onset AS is not uncommon among young patients. Such patients tend to have enthesitis and peripheral arthritis, which may be severe and disabling.

## ANKYLOSING SPONDYLITIS IN MALES AND FEMALES

Clinically, AS is more common in males, with a reported male to female ratio of approximately 2:1 to 3:1. In contrast, studies of patients with nr-axSpA usually show a slight female preponderance.[115] One possible explanation could be that structural changes are less likely to develop in women. Another possibility might be lack of specificity of the ASAS classification criteria.[11] This would cause false-positive inclusion of female patients who fulfill the criteria but do not really have axSpA. Of course, both possibilities are not mutually exclusive.

Disease expression of AS by modified New York criteria is thought to be different in males and females. A case-control study comparing 35 female patients with 70 male patients as controls showed no differences in spinal symptoms, chest expansion, peripheral arthritis, extra-articular manifestations, or functional outcome. The males with AS more often had radiographic spinal changes and hip joint involvement than their female counterparts. There is still some controversy, but overall, there are no significant clinical or radiographic differences between women and men with AS. However, on average, the disease seems to be more severe in men.[116,117]

Female patients with AS have normal fertility.[118] Most patients (50% to 60%) do not experience major changes in disease activity during pregnancy, but an increase in morning stiffness and low back pain, particularly at night, may occur at approximately the 20th week of gestation and last for a few days to weeks.[119] In approximately 50% of patients, an exacerbation of symptoms is seen within the first half year after delivery. Sacroiliitis including complete ankylosis of the SI joints does not constitute a contraindication for vaginal delivery. Epidural anesthesia is usually possible because most patients have a rather short duration of disease and do not have extensive spinal syndesmophytes. The fetal outcome is not impaired in patients with AS. Every pregnancy in patients with this disease should be considered potentially high risk, however, and such pregnancies require close collaboration between rheumatologists and obstetricians.

An uncontrolled study among 612 AS patients (mean age, 50.8 years; 71.6% males) reported a substantial impact on sexual relationships (response rate, 38%). Poor function, depression, disease activity, unemployment, and poor self-efficacy were independently associated with greater impact on patients' sexual relationships.[120]

## OUTCOME

The course of AS is highly variable, characterized by spontaneous remissions and exacerbations. Its prognosis has generally been considered rather favorable. The disease may run a relatively mild or self-limited course. However, the disease may also remain active during many years. Life expectancy is somewhat reduced, particularly after 10 years of disease.[121] A study from Finland indicates that the risk of dying for patients with AS is increased by 50% compared with controls matched for age and gender. Causes of death include complications of the disease such as amyloidosis and spinal fractures, as well as cardiovascular, gastrointestinal, and renal disease.[122] No differences exist between familial and sporadic AS in terms of age at onset, age at diagnosis, or prevalence of peripheral arthritis and acute anterior uveitis.[123]

Functional limitations increase with disease duration. Although structural damage seen on radiographs is clearly associated with physical function and spinal mobility at the group level, individual patients with normal radiographs might exhibit a major reduction in spinal mobility, whereas those with severe radiographic abnormalities might function quite well in everyday tasks.[124]

The functional prognosis of AS is less favorable than was previously thought. Withdrawal from work in those with paid jobs varies from 10% after 20 years of disease duration to 30% after 10 years, depending on the characteristics of the patients included and the social security system considered.[125-128] The age- and sex-adjusted withdrawal rate from labor-force participation was 3.1 times higher among Dutch patients compared with the general population.[128] Older age at disease onset, manual work, lower educational level, and coping strategies characterized by the limitation and pacing of activities were associated with a higher risk for work disability.[126-128] Vocational counseling, job training, easy access to the workplace, and support of colleagues and management may reduce the probability of withdrawal from work.[125,129] Sick leave in those with paid jobs was linked to disease activity and presence of extraspinal disease manifestations.[125,128,130] Patients with peripheral joint involvement are more likely to take sick leave than are AS patients with axial manifestations only.

Overall, the first 10 years of disease are particularly important with respect to subsequent outcome. Most of the loss of function among patients with AS occurs within this period and is associated with the presence of peripheral arthritis, spinal radiographic changes, and development of a so-called *bamboo spine*.[131,132] Although radiographic progression is highly variable among patients, radiographic

evidence of spinal involvement, especially the presence of syndesmophytes, appears to be the primary factor that independently predicts further radiographic progression.[133]

Increasing evidence supports the importance of inflammation in predisposition to radiographic progression. Clinical parameters of inflammation, notably the Ankylosing Spondylitis Disease Activity Score (ASDAS) and CRP, are associated with prognostic risk, especially early in the disease course, which is consistent with MRI data that evaluate prognostic risk of inflammatory lesions in the spine.[58,134,135] This is also consistent with preliminary data from an observational cohort that introduction of anti-TNF therapy early in the disease course may be associated with less risk for radiographic progression. Smoking and NSAID utilization have also been shown to influence prognostic risk, although it is unclear whether this is related to inflammation.[136-138] Biomarkers reflecting connective tissue remodeling (e.g., metalloproteinase 3 and citrullinated vimentin) and formation of bone (e.g., sclerostin and dickkopf-1) have been associated with radiographic progression.[139-142]

The long-term results of total hip replacement in AS are satisfactory. The outcome of 138 total hip replacements and 12 revisions was good or very good in 86% of patients, and 63% of patients had no pain. Mobility was good or very good in 44% of patients. The mean follow-up was 7.5 years (range, 1 to 34 years). Altogether, 69% of the male hip recipients younger than 60 years were at work at the time of the survey.[143]

## ASSESSMENT AND MONITORING

Signs and symptoms such as spinal pain and limitation of motion might be the result of current disease activity or to damage. A plethora of tools is available to assess these dimensions. For example, there are many ways to measure limitation of motion of the lumbar spine. New instruments have been developed to assess various aspects of the disease, including the Bath and Edmonton AS Metrology Indices, the Bath AS Global Index, the BASRI, the Bath AS Disease Activity Index, and the Dougados Functional Index.[144-149] However, standardization and validation of many of these instruments are lacking or incomplete. An international ASAS working group was formed with the aim of selecting, proposing, and testing core sets of measures for different settings.[150] It was thought that a certain set of variables should be targeted to a specific task. For example, when assessing the efficacy of physical therapy, it would not be realistic to include measures of radiographic changes of the spine. Clearly, the set of measures for a drug's disease-modifying capabilities will differ from a set that measures analgesic effectiveness only. Four settings have been defined: disease-controlling anti-rheumatic therapy; symptom-modifying anti-rheumatic drugs, such as NSAIDs; physical therapy; and clinical record keeping in daily practice (Table 75-10).[150] Criteria to assess the response of individual patients have also been developed and validated. These ASAS-20 improvement criteria are frequently used in clinical trials.[151] In addition, more stringent improvement criteria—ASAS-40 and ASAS-5/6—have been proposed,[152] as well as criteria to define partial remission. The three sets of improvement criteria and the partial remission criteria are presented in Table 75-11.[151,152] The recently developed ASDAS enables physicians to define disease activity states and to demonstrate improvement by applying cutoff values.[135]

A needs-based quality-of-life instrument specific for AS has been developed. It is well accepted by patients and easy to perform, and has shown good scaling, psychometric properties, and sensitivity to change.[153,154]

## MANAGEMENT

### KEY POINTS

**NSAIDs, physiotherapy, and patient education are first-line therapy.**

**TNF inhibitors are effective to treat the signs and symptoms in moderate to severe disease. Biologics that target other cytokines, such as IL-17A, also demonstrate clinical efficacy.**

**Some rather weak evidence supports the view that continuous use of NSAIDs may reduce radiographic progression. However, results of studies are conflicting; weighing advantages and disadvantages, it is currently unclear whether or when AS patients should be offered continuous NSAID treatment.**

**TABLE 75-11** Assessment in Ankylosing Spondylitis International Working Group Improvement Criteria and Partial Remission Criteria

| |
|---|
| **ASAS-20 Improvement Criteria** |
| At least 20% improvement and 10 units improvement in 3 of the 4 following domains, without 20% or more worsening and 10 units worsening in the remaining domain: |
| BASFI |
| Morning stiffness |
| Patient global assessment |
| Pain |
| **ASAS-40 Improvement Criteria** |
| At least 40% improvement and 20 units improvement in 3 of the 4 following domains, without any worsening in the remaining domain: |
| BASFI |
| Morning stiffness |
| Patient global assessment |
| Pain |
| **ASAS-5/6 Improvement Criteria** |
| At least 20% improvement in 5 of the 6 following domains: |
| BASFI |
| Morning stiffness |
| Patient global assessment |
| Pain |
| Acute phase reactants |
| Spinal mobility |
| **ASAS Partial Remission Criteria** |
| A value below 20 units in all 4 domains of the ASAS-20 improvement criteria |

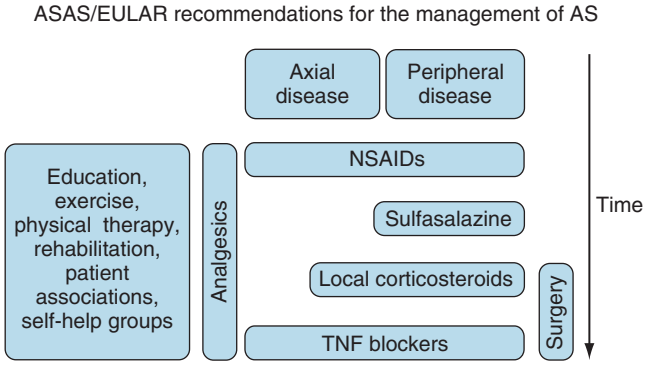

**Figure 75-3** Recommended management of ankylosing spondylitis (AS), based on clinical expertise and research evidence. The disease progression with time moves vertically from top to bottom. These recommendations were developed before the availability of secukinumab. Secukinumab is approved but was not available at the time of these recommendations. ASAS/EULAR, Assessment in Ankylosing Spondylitis/European League against Rheumatism; NSAIDs, nonsteroidal anti-inflammatory drugs; TNF, tumor necrosis factor.

Updated recommendations that emphasize the key evidence-based components of disease management have been compiled[154a,155,156] (Tables 75-12 and 75-13; Figure 75-3). Most patients do not experience significant extraskeletal manifestations except for acute anterior uveitis, which occurs in approximately 30% to 40% of patients. The number of patients who have experienced uveitis increases with disease duration. Usually, this eye disease can be well managed with eye drops that contain corticosteroids to reduce inflammation and with pupil-dilating, mydriatic agents to prevent or diminish synechiae (when the iris adheres to the cornea or lens). At the outset, patients should be warned that acute anterior uveitis may occur at any time during the course of the disease.

The treatment objectives in AS are to relieve pain, stiffness, and fatigue and to maintain good posture and good physical and psychosocial functioning.[157] Evidence is lacking that any of the conventional DMARDs, including sulfasalazine and methotrexate (MTX) alter or inhibit the inflammation seen in the spine and entheses in AS.

A full explanation of the disease, its course, possible complications (e.g., acute anterior uveitis), and its prognosis is very helpful to achieve treatment adherence by the patient. Self-help groups provide important information and social support. In addition, patient organizations often provide access to hydrotherapy and group physiotherapy. Exercises are a mainstay of treatment. Preferably, they should be started after a hot shower or a hot bath. Swimming and extension-promoting exercises or sporting activities such as volleyball or cross-country skiing are appropriate. These activities counteract the kyphotic effects of pain and fatigue on posture and reduce stiffness. Patients should avoid vigorous or contact sports if the spine has become fused or osteoporotic because such a spine is susceptible to fracture.

Appliances such as driving mirrors may improve comfort and safety, especially if there is considerable involvement of the cervical spine. In that case, appropriate neck support is also required to reduce the risk of fractures in the vulnerable osteoporotic cervical spine as a consequence of traffic accidents.

## Physiotherapy

Evidence indicates that physiotherapy in the form of exercises is effective, at least in the short term (as long as 1 year). In a randomized, controlled trial, a program of supervised physiotherapy in groups was superior to individualized programs in improving thoracolumbar mobility and fitness. The program, which consisted of hydrotherapy, exercises, and sporting activities twice weekly for 3 hours per session, resulted in improved overall health and less stiffness, as reported by the patient.[158] An intensive 3-week SpA exercise therapy program resulted in marked improvement in both subjective and objective assessments that lasted for as long as 9 months. Health resource use, in particular NSAID use and sick leave, was significantly reduced during this 9-month follow-up period. The clinical benefits of such treatments can be achieved at acceptable costs.[159,160] A Cochrane Review concluded that a home exercise program is better than no intervention, supervised group physiotherapy is better than home exercises, and that combined inpatient spa-exercise therapy followed by supervised outpatient weekly group physiotherapy is better than weekly group physiotherapy alone (level A evidence) (Table 75-14)[161] The tendency toward positive effects of physiotherapy in the management of AS calls for further research in this field. New trials should also address other physiotherapy interventions commonly used in clinical practice.

**TABLE 75-12** First Update of the ASAS/EULAR Recommendations for the Management of Ankylosing Spondylitis

| |
|---|
| The over-reaching principles of the management of patients with ankylosing spondylitis (AS) are: |
| AS is a potentially severe disease with diverse manifestations, usually requiring multidisciplinary treatment coordinated by the rheumatologist |
| The primary goal of treating the patient with AS is to maximize long-term health-related quality of life through control of symptoms and inflammation, prevention of progressive structural damage, preservation/normalization of function, and social participation |
| Treatment of AS should aim at the best care and must be based on a shared decision between the patient and the rheumatologist |
| The optimal management of patients with AS requires a combination of nonpharmacologic and pharmacologic treatment modalities |
| **General Treatment** |
| The treatment of patients with AS should be tailored according to: |
| The current manifestations of the disease (axial, peripheral, entheseal, extra-articular symptoms and signs) |
| The level of current symptoms, clinical findings, and prognostic indicators |
| The general clinical status (age, gender, comorbidity, concomitant medications, psychosocial factors) |
| **Disease Monitoring** |
| The disease monitoring of patients with AS should include: |
| Patient history (e.g., questionnaires) |
| Clinical parameters |
| Laboratory tests |
| Imaging |
| All according to the clinical presentation as well as the ASAS core set |
| The frequency of monitoring should be decided on an individual basis depending on: |
| Course of symptoms |
| Severity |
| Treatment |
| **Nonpharmacologic Treatment** |
| The cornerstone of nonpharmacologic treatment of patients with AS is patient education and regular exercise |
| Home exercises are effective. Physical therapy with supervised exercises, land or water based, individually or in a group, should be preferred as these are more effective than home exercises |
| Patient associations and self-help groups may be useful |
| **Extra-articular Manifestations and Comorbidities** |
| The frequently observed extra-articular manifestations (e.g., psoriasis, uveitis, and inflammatory bowel disease) should be managed in collaboration with the respective specialists |
| Rheumatologists should be aware of the increased risk of cardiovascular disease and osteoporosis |
| **Nonsteroidal Anti-inflammatory Drugs (NSAIDs)** |
| NSAIDs, including coxibs, are recommended as first-line drug treatment for AS patients with pain and stiffness |
| Continuous treatment with NSAIDs is preferred for patients with persistently active, symptomatic disease |
| Cardiovascular, gastrointestinal, and renal risks should be taken into account when prescribing NSAIDs |
| **Analgesics** |
| Analgesics, such as paracetamol and opioid (like) drugs, might be considered for residual pain after previously recommended treatments have failed, are contraindicated, and/or are poorly tolerated |
| **Glucocorticoids** |
| Corticosteroid injections directed to the local site of musculoskeletal inflammation may be considered |
| The use of systemic glucocorticoids for axial disease is not supported by evidence |
| **Disease-Modifying Anti-rheumatic Drugs (DMARDs)** |
| There is no evidence for the efficacy of DMARDs, including sulfasalazine and methotrexate, for the treatment of axial disease |
| Sulfasalazine may be considered in patients with peripheral arthritis |
| **Anti–Tumor Necrosis Factor (TNF) Therapy** |
| Anti-TNF therapy should be given to patients with persistently high disease activity despite conventional treatments, according to the ASAS recommendations |
| There is no evidence to support the obligatory use of DMARDs before or concomitant with anti-TNF therapy in patients with axial disease |
| There is no evidence to support a difference in efficacy of the various TNF inhibitors on the axial and articular/entheseal disease manifestations, but in the presence of inflammatory bowel disease, a difference in gastrointestinal efficacy needs to be taken into account |
| Switching to a second TNF blocker might be beneficial, especially in patients with loss of response |
| There is no evidence to support the use of biologic agents other than TNF inhibitors in AS |
| **Surgery** |
| Total hip arthroplasty should be considered in patients with refractory pain or disability and radiographic evidence of structural damage, independent of age |
| Spinal corrective osteotomy may be considered in patients with severe disabling deformity |
| In patients with AS and an acute vertebral fracture, a spinal surgeon should be consulted |
| **Changes in the Disease Course** |
| If a significant change in the course of the disease occurs, causes other than inflammation, such as a spinal fracture, should be considered, and appropriate evaluation, including imaging, should be performed |

These recommendations were developed before the availability of secukinumab. Secukinumab is approved but was not available at the time of these recommendations.

ASAS, Assessment in Ankylosing Spondylitis; EULAR, European League against Rheumatism.

From van der Heijde D, Sieper J, Maksymowych WP, et al: 2010 update of the international ASAS recommendations for the use of anti-TNF agents in patients with axial spondyloarthritis. *Ann Rheum Dis* 70:905–908, 2010.

**TABLE 75-13** SPARTAN Key Recommendations for the Treatment of Patients with Ankylosing Spondylitis or Nonradiographic Axial Spondyloarthritis

| |
|---|
| In adults with active AS, we strongly recommend treatment with NSAIDs over no treatment with NSAIDs. |
| In adults with active AS despite treatment with NSAIDs, we strongly recommend treatment with TNF-i over no treatment with TNF-i.* |
| In adults with active AS, we do not recomment any particular TNF-i as the preferred choice, except for patients with concomitant IBD or recurrent iritis. |
| In adults with active AS and IBD, we strongly recommend treatment with TNF-i monoclonal antibodies over treatment with etanercept. |
| In adults with active AS, we strongly recommend against treatment with systemic glucocorticoids. |
| In adults with active AS, we strongly recomment treatment with physical therapy over no treatment with physical therapy. |
| In adults with active AS and advanced hip arthritis, we strongly recomment treatment with total hip arthroplasty over no surgery. |
| In adults with active nonradiographic axial SpA despite treatment with NSAIDs, we conditionally recommend treatment with TNF-i over no treatment with TNF-i. |

*These recommendations were developed before the availability of anti-IL-17 antibodies. Anti-IL-17 antibodies are approved but were not available at the time of these recommendations.

**TABLE 75-14** Cochrane Review of Physiotherapeutic Interventions and Spondyloarthritis Therapy for Patients with Ankylosing Spondylitis: Conclusions

| |
|---|
| Home exercise programs are better than no intervention |
| Supervised group physiotherapy is better than home exercise |
| Combined inpatient spondyloarthritis and exercise therapy followed by supervised outpatient weekly group physiotherapy is better than weekly group physiotherapy alone |

From Dagfinrud H, Kvien TK, Hagen KB: Physiotherapy interventions for ankylosing spondylitis. *Cochrane Database Syst Rev* (4):CD002822, 2004.

Moreover, the impact on physical functioning of physiotherapy in patients who respond well to biologics needs to be assessed.

Lying prone for 15 to 30 minutes once or several times a day is useful to reverse the tendency toward kyphosis, which is aggravated by pain and fatigue, as well as flexion contractures of the hip joints. Patients should sleep fully supine on a firm mattress with only a small neck-support pillow.

## Pharmacotherapy

### Nonsteroidal Anti-inflammatory Drugs

The efficacy and effectiveness of NSAID therapy for the alleviation of symptoms have been well established (level A evidence). When patients take them for prolonged periods of as long as a year, there may be improvement in spinal mobility and acute phase reactants.[162] Many NSAIDs are effective in patients with AS, and no NSAID has documented superiority in terms of efficacy. Selective cyclooxygenase-2 (COX-2) inhibitors have similar efficacy to conventional NSAIDs (level A evidence).[163] A nonselective NSAID, such as naproxen, is appropriate initial therapy for AS. A COX-2–selective agent (coxib) may be used in the presence of risk factors for peptic ulceration, although both categories of NSAIDs may exacerbate inflammatory bowel disease. Once-daily drug regimens may improve patient compliance. As long as 2 weeks may be required to demonstrate maximal symptomatic benefit from an NSAID. If symptomatic relief is inadequate, a switch to another NSAID is often worthwhile; failure of two NSAIDs should prompt an exploration of other management strategies. In early disease, 1000 mg of naproxen daily was sufficient to put 35% of patients with imaging-positive axial SpA into partial remission, and 57% of patients had an ASAS-40 response.[164] This trial compared naproxen with infliximab, so the placebo rates are unknown.

Given the gastrointestinal and cardiovascular risks of taking NSAIDs or coxibs, one must consider whether this treatment should be on a daily or an "on-demand" basis. A 2-year randomized, prospective, controlled trial in patients with AS compared the efficacy of continuous NSAID therapy with that of intermittent on-demand use. The results suggest that continuous therapy retards radiographic disease progression.[60] A reanalysis of this trial showed that patients with an elevated CRP benefited most in terms of reducing radiographic progression.[165] This study's results agree with an older retrospective study that also suggested a possible disease-controlling effect of continuous therapy.[166] Another observational study from a longitudinal cohort has also found that NSAIDs retard radiographic progression of disease.[167] These findings require confirmation in further randomized trials that eliminate the biases that can be present in observational studies. One randomized multicenter trial showed that continuous treatment with diclofenac over 2 years did not reduce radiographic progression compared with on demand treatment in AS.[154b]

Whether patients should take NSAIDs primarily for retardation of radiographic progression, whether or not they are on a TNF inhibitor, is not definitively known at present. However, based on these data, patients at high risk of radiographic progression (e.g., those with pre-existing syndesmophytes and/or raised CRP) could take continuous NSAIDs to try to reduce their progression rate. This is an individual decision and one that should take into account the risk of radiographic progression, the strength of evidence we have for the effect of NSAIDs on modifying this risk, and the risk of gastrointestinal and cardiovascular complications that NSAID contribute.

### Second-Line Drugs

Borrowing well-established concepts in the treatment of RA, disease-controlling therapy for AS has been defined as an agent that decreases inflammatory manifestations of disease, sustains or improves function, and prevents or decreases the rate of progression of structural damage. Although most of the second-line agents developed

primarily for RA have been studied in patients with AS, none can be considered disease controlling in AS. Most data are available for sulfasalazine, which was first proposed as a therapy for AS in 1984, based on the common association between inflammatory bowel disease and SpA, the description of inflammatory lesions in the ileum of patients with SpA, and its success in the treatment of intestinal inflammation.[168] A total of 11 double-blind, placebo-controlled trials have been published, as well as two meta-analyses. The results of the two largest trials were consistent in demonstrating no significant benefit for sulfasalazine in AS, although subgroup analysis showed that patients with (peripheral) polyarthritis—mostly those with psoriatic arthritis, but also AS patients with peripheral joint involvement—had a significant but modest response.[169,170] An important limitation in most of these studies was the long disease duration (>10 years) of recruited patients, and it has been suggested that early disease may be more responsive to therapy. However, a 24-week placebo-controlled trial that recruited 230 patients who met the European Spondyloarthropathy Study Group (ESSG) criteria for SpA and who had symptom duration of less than 5 years confirmed that sulfasalazine was ineffective.[171] The most recent meta-analysis, based on 11 trials, concluded that this agent has a significant impact only on the ESR and the severity of spinal stiffness (level A evidence).[172] The primary indication for the use of sulfasalazine in routine practice is a patient who has concomitant peripheral arthritis and has had an inadequate response to NSAIDs and physical modalities.

The evaluation of MTX in AS has been limited to case reports and open analyses. These studies have included limited numbers of patients for periods of 6 months to 3 years, at doses from 7.5 to 15 mg weekly. The results have been mixed, with some benefit noted in patients with concomitant peripheral arthritis. Two small placebo-controlled trials assessed MTX in doses of 10 and 7.5 mg weekly for 24 weeks, with contradictory findings.[173,174] A meta-analysis concluded that there was no evidence of efficacy and that higher-quality trials, larger sample sizes, longer durations of treatment, and higher dosages of MTX were necessary before any definitive conclusions could be drawn (level B evidence).[175] Corticosteroids may be effective for local intra-articular treatment in AS, including the SI joints, if given under fluoroscopic guidance (level B evidence). High-dose intravenous pulse corticosteroids have been studied in trials and found to have effect in patients with AS who have flared.[176,177] This therapy was used primarily in treatment-resistant patients before the availability of TNF inhibitors. Systemic oral steroids for AS treatment have been assessed in a 2-week placebo-controlled trial of daily 50 mg prednisolone, 20 mg prednisolone, or placebo. The study found no different in primary endpoint (50% improvement in BASDAI) in either treatment group, but a difference was noted in secondary endpoints (mean BASDAI, BASMI, ASDAS). The mean decrease in BASDAI in the 50-mg prednisolone group was higher compared with placebo (2.39 vs. 0.66, respectively).[178] Leflunomide has been studied in AS, and although an open-label study suggested a benefit in patients with peripheral arthritis, a small placebo-controlled study reported no benefit (level B evidence).[179,180] A controlled dose-response (60 mg vs. 10 mg) evaluation of a bisphosphonate vs. pamidronate, given intravenously on a monthly basis for 6 months, showed evidence of symptomatic efficacy, primarily in patients with only axial disease (level B evidence).[181] The bisphosphonate neridronate was compared with infliximab in a 6-month, open-label uncontrolled study, and no difference was found between these two treatments in their primary efficacy measure: BASDAI reduction. Both agents showed clinically significant improvements compared with baseline.[182]

Thalidomide has been used in two open-label studies in AS because of its known anti-TNF effect, through enhanced degradation of the TNF messenger ribonucleic acid. In a Chinese study, improvement was reported in 80% of patients, with deterioration 3 months after treatment discontinuation. Frequent side effects are drowsiness, constipation, and dizziness (level B evidence). Particular caution is required because of other major thalidomide-associated side effects, such as teratogenicity and peripheral neuropathy.[183]

Considering just nr-axSpA, there is a paucity of evidence regarding the effect of traditional oral DMARDs, but their effect is likely to be similar or better to established AS. As with other agents in rheumatology, early institution of therapy may increase response rates, but this fact is not currently known. Better reporting of separate patient groups (AS and nr-axSpA) in trials will yield more conclusive results.

## Biologic Therapies

TNF inhibitors have revolutionized the treatment of AS. Their introduction was based on the finding of TNF expression in SI joint biopsies of AS patients, the observation that overexpression of TNF leads to sacroiliitis in animal models, and earlier clinical trial data demonstrating the efficacy of one TNF inhibitor, infliximab, in Crohn's disease. Five TNF inhibitors are of proven benefit in AS according to pivotal phase III trials (level A evidence): infliximab, etanercept, adalimumab, certolizumab, and golimumab. Infliximab is an $IgG_1$ chimeric monoclonal antibody, with the Fab portion derived from the mouse. It is given in a dose of 5 mg/kg every 6 to 8 weeks after loading at 0, 2, and 6 weeks. Etanercept is a recombinant TNF receptor $IgG_1$ fusion protein that is self-administered by subcutaneous injection either once (50 mg) or twice (25 mg) weekly. Adalimumab and golimumab are human monoclonal antibodies that are self-administered by subcutaneous injection on alternate weeks (40 mg) or monthly (50 mg), respectively. Certolizumab is a pegylated Fab fragment of a humanized TNF inhibitor monoclonal antibody that is given as a subcutaneous injection either as a 200-mg fortnightly or a 400-mg monthly dose. None of these agents require concomitant therapy with MTX.

In phase III trials in patients with AS all of these agents demonstrated ASAS-20 response rates of 55% to 60% and ASAS-40 response rates of 45% to 50%.[184-188] Even higher response rates have been observed in patients with nr-axSpA and short disease duration who received adalimumab or infliximab in placebo-controlled or active comparator trials.[164,189,190] Partial remission rates of 62% at week 28 were seen in a trial of imaging positive axSpA comparing infliximab with 1000 mg of naproxen in those with disease duration of less than 2 years. This is superior to 22% partial remission rate at week 24 in the trial of infliximab in

established AS.[164,184] Response rates in nr-axSpA are also improved in those with an elevated CRP or an MRI scan showing inflammatory lesions.[191]

Improvement in symptoms is evident by 2 to 4 weeks and is sustained as long as the patient remains on treatment. Virtually all patients with AS relapse by 6 months after discontinuation of treatment.[192] However, withdrawal of therapy in nr-axSpA patients treated early results in a substantial minority (30% to 40%) maintaining remission or partial remission at or beyond 6 months.[193,194] A trial of imaging-positive nr-axSpA patients who had symptoms for less than 2 years and were treated with infliximab for 6 months, 87% to 94% had low disease activity, and 40% to 48% maintained partial remission 6 months after withdrawal of infliximab therapy.[193]

Significant improvement is also observed in function, spinal mobility, peripheral synovitis, enthesitis score, and quality of life with TNF inhibitors. Sick leave and work disability are reduced. Only two patients with AS need to be treated for one to experience at least 50% improvement in disease activity (95% CI, 1 to 6). Objective parameters of disease activity that show improvement include acute phase reactants, synovial histopathology, and MRI features of inflammation in the spine and SI joints.[195] Response to treatment in patients with established AS appears to be increased in those with high disease activity and worse in those with long disease duration, impaired function, and no discernible evidence of inflammation on MRI.[196] Adverse events in patients with AS are no different from those reported in patients with RA, and infusion reactions in patients receiving infliximab have been no more frequent than in patients with RA on concomitant MTX. All TNF inhibitors are effective for psoriasis, and the monoclonal anti-TNF antibodies, infliximab and adalimumab, also have demonstrated efficacy in both uveitis and colitis. Patients who do not respond to one TNF inhibitor may respond to an alternative TNF inhibitor.

Some observational data suggests TNF inhibitors may reduce radiographic progression during a long time period (8 to 10 years).[58,197] The evidence supporting this effect is still preliminary, and based on observational data that is prone to bias. Therefore this requires additional validation.

Recommendations for the use of anti-TNF therapies in axSpA have been developed (Table 75-15).[154a,173,198] These new therapeutic modalities identify important clinical questions to be answered by further research. All of the anti-TNF agents examined to date have symptom-modifying properties, but their long-term disease-controlling effects in terms of preventing structural damage have yet to be definitively demonstrated.

No other biologic therapies are approved for AS or axSpA. Trials of rituximab in AS have shown some efficacy in patients who are TNF inhibitor naïve, but had poor results in TNF inhibitor failure patients. Trials of abatacept (CTLA4-Ig), tocilizumab (anti–IL-6R), sarilumab (anti–IL-6R) and anakinra (anti–IL-1) have failed to show efficacy in AS or axSpA.

The genetic association between AS and the IL-23R gene and the proven functional role that IL-23R genetic variants have on immune system function suggests that agents targeting IL-23 and the downstream cytokine IL-17 hold great promise.

Secukinumab has now been approved for use in AS by the FDA; abstract data reports ASAS20 response rates at week 16 of 61.1% with secukinumab 150 mg versus 28.4% with placebo treatment. The approved dosage includes both a regimen with a loading dose and one without, with 150 mg every four weeks being the maintenance dose. ASAS40 response in the same trial was 36.1% for secukinumab versus 10.8% for placebo. Because of the recent nature of the approval, the place of secukinumab in treatment algorithms is yet to be defined. A phase II trial of ustekinumab (anti–IL-12/23p40) has shown efficacy, and definitive phase III trial data is awaited.

## Anterior Uveitis

TNF inhibitors have been shown to reduce the occurrence of flares of acute anterior uveitis in AS patients.[199,200] The rate of flares was reduced by 51% in all patients and 68% in patients with recent uveitis in a prospective trial of adalimumab.[200] Combined data from 4 trials of infliximab and etanercept showed a reduction from 15.6 flares per 100 patient-years in the control groups to 6.8 fares per 100 patient-years in the TNF inhibitor–treated groups.[199] Other trials have found broadly similar rates of reduction in flares with TNF inhibitors.[201,202]

Retrospective studies suggested that the fusion protein etanercept did not have the same positive effect on uveitis reduction as the monoclonal antibodies, and perhaps even caused an increase in uveitis flares.[203-205] An analysis of eight etanercept trials showed that the rate of uveitis on etanercept was less than placebo (8.6 and 19.3 per 100 patient-years, respectively). In active comparator trials against sulphasalazine, the rate of uveitis on etanercept was numerically lower (10.7 per 100 patient-years) but not statistically significantly different to the flare rate on sulphasalazine (14.7 per 100 patient-years).[202] Based on retrospective analyses, etanercept probably has a reduced level of efficacy on uveitis compared with the monoclonal antibodies, but head-to-head studies have not been conducted to determine this definitively and if so the magnitude of difference.[203,206] Flares of uveitis happen on all of the TNF inhibitors, but if they are recurrent or persistent, then a change of TNF inhibitor may be warranted.

There is some evidence that oral anti-rheumatic agents are effective at decreasing the rate of uveitis in SpA patients. In a small open trial of MTX that assessed 9 patients, the mean recurrence rate of uveitis in the year before MTX use was 3.4, and this dropped to 0.9 during the following year.[207] In this study, most patients were on 7.5 mg of MTX per week. Two studies have shown that sulphasalazine also reduces the flare rate of uveitis. In a 3-year randomized controlled study, the reduction in mean attacks per patient per year was 0.2 to 0.8.[208] An observational study of flare rate presulphasalazine and postsulphasalazine treatment showed a reduction from 3.4 flares per year to 0.9 flares per year.[209] There is also some suggestive data that NSAIDs reduce flares of uveitis.[210]

## Surgery

Involvement of the hip joint may cause serious disability. After 30 years of disease duration, 12% to 25% of patients

**TABLE 75-15** 2010 Update of Recommendations for the Use of Anti–Tumor Necrosis Factor Agents in Patients with Axial Spondyloarthritis

| RECOMMENDATION | |
|---|---|
| **Patient Selection** | |
| Diagnosis | Patients fulfilling modified New York Criteria for definitive AS* or the ASAS criteria for axial SpA |
| Active disease | Active disease for ≥4 wk<br>BASDAI ≥ 4 (0-10)† and a positive expert opinion‡ |
| Treatment failure | All patients should have had adequate therapeutic trials of at least two NSAIDs. An adequate therapeutic trial is defined as at least two NSAIDs over a 4-wk period in total at maximum recommended or tolerated anti-inflammatory dose unless contraindicated<br>Patients with predominantly axial manifestations do not have to take DMARDs before anti-TNF treatment can be started<br>Patients with symptomatic peripheral arthritis should have an insufficient response to at least one local steroid injection if appropriate and should normally have had an adequate therapeutic trial of a DMARD, preferably sulfasalazine<br>Patients with symptomatic enthesitis must not have responded to appropriate local treatment |
| **Assessment of Disease** | |
| *ASAS Core Set of Daily Practice* | |
| Physical function (BASFI or Dougados Functional Index)<br>Pain (VAS for spine at night from AS in the past week and VAS for spine from AS in the past week)<br>Spinal mobility (chest expansion, modified Schober's test and occiput-to-wall distance, and lateral lumbar flexion)<br>Patient's global assessment (VAS for the past week)<br>Stiffness (duration of morning spine stiffness in the past week)<br>Peripheral joints and entheses (number of swollen joints [44 total], enthesitis score such as developed in Maastricht, Berlin, or San Francisco)<br>Acute phase reactants (erythrocyte sedimentation rate or C-reactive protein)<br>Fatigue (VAS) | |
| *BASDAI* | |
| VAS for overall level of fatigue or tiredness in the past week<br>VAS for overall level of AS neck, back, or hip pain in the past week<br>VAS for overall level of pain or swelling in joints other than neck, back, or hips in the past week<br>VAS for overall discomfort from any areas tender to touch or pressure in the past week<br>VAS for overall level of morning stiffness from time of awakening in the past week<br>Duration and intensity (VAS) of morning stiffness from time of awakening (up to 120 min) | |
| **Assessment of Response** | |
| Responder criteria | BASDAI: 50% relative change or absolute change of 2 (on 0-10 scale) *and* expert opinion in favor of continuation |
| Time of evaluation | After at least 12 wk |

These recommendations were developed before the availability of secukinumab. Secukinumab is approved but was not available at the time of these recommendations.

*Modified New York criteria (van der Linden et al, 1984): radiologic criterion (sacroiliitis, grade ≥2 bilaterally or grade 3 to 4 unilaterally) and at least two out of three clinical criteria (low back pain and stiffness for more than 3 mo that improves with exercise but is not relieved by rest; limitation of motion of the lumbar spine in both the sagittal and frontal planes; limitation of chest expansion relative to normal values correlated for age and sex).

†BASDAI assessed on a 0-10 VAS or NRS.

‡The expert is a doctor, usually a rheumatologist, with expertise in inflammatory back pain and the use of biologic agents. Experts should be locally defined. An expert opinion should consider clinical features (history and examination) as well as either serum acute phase reactant levels or imaging results, such as radiographs demonstrating rapid progression or MRI scans indicting inflammation.

ASAS core set for daily practice: physical function (BASFI); pain (VAS/NRS, last week; spine at night, caused by AS and VAS/NRS, last week; spine caused by AS); spinal mobility (chest expansion, cervical rotation, occiput-to-wall distance, modified Schober's test, and lateral lumbar flexion or BASMI); patient's global assessment (VAS/NRS, last week); stiffness (duration of morning stiffness, spine, VAS/NRS, last week); peripheral joints and entheses (number of swollen joints [44-joints count], enthesitis score such as developed in Maastricht, Berlin, or San Francisco); acute phase reactants (preferably C-reactive protein); fatigue (VAS/NRS).

AS, Ankylosing spondylitis; ASAS, Assessment of SpondyloArthritis (International Society); BASDAI, Bath Ankylosing Spondylitis Disease Activity Index; BASFI, Bath Ankylosing Spondylitis Functional Index; BASMI, Bath Ankylosing Spondylitis Metrology Index; DMARD, disease-modifying anti-rheumatic drug; NRS, numeric rate scale; NSAIDs, nonsteroidal anti-inflammatory drugs; SpA, axial spondyloarthritis; TNF, tumor necrosis factor; VAS, visual analogue scale.

From van der Heijde D, Sieper J, Maksymowych WP, et al: 2010 update of the international ASAS recommendations for the use of anti-TNF agents in patients with axial spondyloarthritis. *Ann Rheum Dis* 70:905–908, 2010.

have at least one hip replaced.[211] Ectopic bone formation may occur, with the rate of heterotopic ossification reported to be 30% in one study.[212,213] One large study of cemented implants with more than 10 years of follow-up showed 96% had low pain scores, and implant survival was excellent.[214,215] Cemented implants generally have a longer life than non-cemented implants.

Vertebral osteotomy may be required in selected cases to correct marked flexion deformity when forward vision is severely impaired. Diaphragmatic herniation may result from the procedure.

In patients with AS, careful consideration of neck involvement is required pre-operatively, including imaging. General anaesthesia needs to be planned well because it requires intubation that involves neck manipulation. These movements may increase the risk of fracture through syndesmophytes or osteoporotic vertebrae. If there is extensive cervical spine disease, special positioning may be required because of kyphosis. Respiratory assessment is also important in established disease because lung function may be adversely affected.

## Osteoporosis

Screening for osteoporosis should occur in those with longer disease duration (>10 years), especially if they have active

disease. Dual energy x-ray (DEXA) scans are appropriate screening tool, but care must be exercised in assessing the lumbar spine measurements because syndesmophytes can artifactually increase bone mass density (BMD) readings. Lateral and volumetric DEXA images may improve the usefulness of lumbar DEXA for assessment.[216] Once diagnosed with osteoporosis, secondary causes or exacerbating factors should be screened for, including hyperthyroidism, hypogonadism, and vitamin D deficiency.

Currently, it is unclear whether any specific antiosteoporotic to prevent spinal fractures therapy, such as bisphosphonates or denosumab, is effective.[76] Reducing disease activity of AS might be more promising in controlling osteoporosis of the vertebral spine. In a 3-year study of 111 patients with AS, treatment with TNF inhibitors has been shown to increase BMD of the spine and hip.[217]

## CONCLUSION

Better understanding of AS genetics has very much improved our knowledge about the pathogenesis of the disease. The spectrum of AS is wider than AS by modified New York criteria. Nonradiologic AS is, however, more heterogeneous than radiologic AS. Inappropriate use of axSpA classification criteria for diagnostic purposes increases the risk of false-positive labeling of individual patients as nonradiologic AS or axSpA. NSAIDs, physiotherapy, and patient education remain first-line therapy. It is currently unclear whether early suppression of inflammation with biologic treatment decreases the risk for new bone formation of the axial skeleton.

CHAPTER 76

# Undifferentiated Spondyloarthritis

John D. Carter • Alan P. Hudson

**KEY POINTS**

- **Undifferentiated spondyloarthritis can have both peripheral and axial features.**
- **Undifferentiated spondyloarthritis is a provisional diagnosis—many cases will evolve into other forms of spondyloarthritis.**
- **Treatment of undifferentiated spondyloarthritis depends on whether axial or peripheral disease is predominant.**

In 1978, a group of inflammatory arthritides that were rheumatoid factor–negative and shared clinical and radiographic features were recognized as a unified entity.[1] These originally were termed *seronegative polyarthritis* but are now known as the *spondyloarthritides* (SpA). Although the SpAs share overlapping features, enough phenotypic heterogeneity exists to permit subclassification. Currently recognized subtypes include ankylosing spondylitis (AS), psoriatic arthritis (PsA), inflammatory bowel disease–related arthritis, reactive arthritis (ReA), and undifferentiated SpA. The term *undifferentiated spondyloarthritis* (uSpA) is used to designate patients with clinical and radiographic features consistent with the SpAs but who do not fulfill the criteria for any of the established disease categories. More recently it has been suggested that these subtypes represent different presentations of one disorder, rather than related but distinct entities.[2] Whether or not these are distinct subtypes, or whether they truly represent one disease process, may have important implications for clinical practice.

Several classification criteria now exist for the SpAs. In 1991, the European Spondyloarthropathy Study Group (ESSG) criteria were developed to establish criteria for the SpAs[3] (Figure 76-1). These criteria have been demonstrated to be 87% sensitive and specific for the diagnosis of SpA. They are, however, somewhat less well suited for diagnosis of early disease but extremely useful for established disease. In 1995, the Amor criteria for SpA were developed[4] (Table 76-1). These are similar to the ESSG criteria but include the human leukocyte antigen (HLA)-B27 antigen. Other classification criteria that have been proposed include the Calin and Berlin criteria[5,6] (Tables 76-1, 76-2 and 76-3). More recently, the Association of SpondyloArthritis International Society (ASAS) developed classification criteria[7] (Figure 76-2). These divide the SpAs into axial or peripheral disease, and more emphasis was placed on the clinical presenting features along with advanced imaging, specifically MRI, in an attempt to classify patients earlier. These classification criteria sets are primarily intended to facilitate research, allowing for rather homogeneous study populations, but they can be used as a guide in clinical practice.

## EPIDEMIOLOGY

Because of the nature of the diagnosis, data regarding the incidence and prevalence of uSpA are limited and variable. The general prevalence of SpA in Caucasian populations is estimated to be 0.5% to 2.0%.[8] However, recent data from the Centers for Disease Control and Prevention's National Health and Nutrition Examination Survey (NHANES) program suggests a higher prevalence. In this survey, the frequency of chronic back pain has risen to 19.4%. with nearly one-third of this number having inflammatory back pain; of these, 1% to 1.4% of the adult U.S. population may have axial spondyloarthritis.[9] These same survey data suggest that the prevalence of inflammatory back pain does not differ significantly among age groups or between genders; non-Hispanic white individuals are significantly more likely to have it compared with non-Hispanic blacks.[10] Interestingly, these same data demonstrate a decreasing frequency of HLA-B27 antigen with increasing age, suggesting a negative impact on long-term survival. The true prevalence of uSpA is difficult to assess quantitatively in these or other groups because of a lack of specific diagnostic criteria, and the fact that it is often unrecognized. This might be particularly true of uSpA patients who are seen primarily with peripheral symptoms.

In spite of these limitations, a few studies have attempted to define the prevalence of uSpA. A large study in Germany demonstrated the overall prevalence of SpA at 1.9%, with AS the most common type (0.86%), followed by uSpA (0.67%).[11] A prospective cohort study that followed 175 patients in a dedicated outpatient SpA clinic classified 23% of patients with uSpA.[12] Another report suggested that uSpA is more than twice as common as AS: 40% of study patients included had uSpA.[13] uSpA was demonstrated in 16.1% of patients with SpA in a study in Spain,[14] 17.8% in Sweden,[15] and 28.2% of early-stage SpA multiracial patients.[16] uSpA also has been associated with HIV infection, with a prevalence of 2.2% to 11.1%.[17] As described previously, uSpA may be the most underdiagnosed subtype of SpA. Another study in Spain evaluated 514 patients with anterior uveitis and found that 53% of these patients were not diagnosed with SpA until after their first episode of uveitis. Of patients who were undiagnosed, 91% had uSpA.[18]

The disease in many patients with uSpA will progress to one of the better defined subtypes if followed up with time.

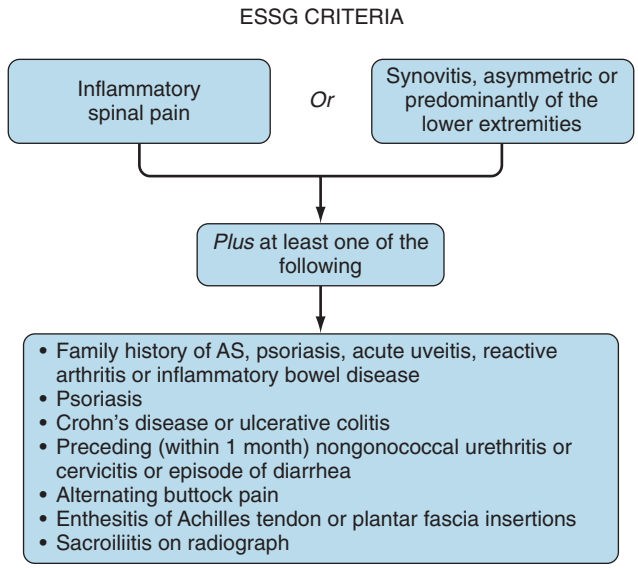

**Figure 76-1** According to the European Spondyloarthropathy Study Group (ESSG) criteria, for a patient to be classified as having spondyloarthritis, he or she has to satisfy one of two entry criteria: inflammatory spinal pain or synovitis (typically asymmetric synovitis, predominantly of the lower limbs). If one or both are present, the patient must have at least one of the features in the bottom box to fulfill the classification criteria. Inflammatory back pain: Back pain is considered inflammatory if four of the following five criteria are found: (1) onset of back discomfort before the age of 40 years, (2) insidious onset, (3) persistence for at least 3 months, (4) association with morning stiffness, and (5) improvement with exercise. AS, Ankylosing spondylitis; ReA, reactive arthritis. *(From Dougados M, van der Linden S, Juhlin R, et al: The European spondyloarthropathy study group preliminary criteria for the classification of spondyloarthropathy.* Arthritis Rheum *34:1218–1227, 1991; and Gomariz EM, del M, Guijo VP, et al: The potential of ESSG spondyloarthropathy classification criteria as a diagnostic aid in rheumatological practice.* J Rheumatol *29:326–330, 2002.)*

In a Brazilian cohort of patients with uSpA and a predominance of female patients, peripheral symptoms were the most prevalent at disease onset, followed by a high frequency of axial manifestations during an 8-year follow-up period.[19] In this same cohort after 2.5 years of follow-up, 16.7% were classified with AS and 2.7% with PsA. A similar study with a predominance of males demonstrated similar progression rates of 24.3% and 2.7% to AS and PsA, respectively.[20] HLA-B27 positivity and buttock pain are significant predictors of progression. For patients with uSpA that transitions to AS, radiographic sacroiliitis can take years to develop[21]; however, the disease burden is similar with and without radiographic sacroiliitis.[22,23]

Although the disease in patients with uSpA can progress, some also experience spontaneous resolution of symptoms. In the same study referenced previously demonstrating that uSpA can progress to AS or PsA, 22.5% of uSpA patients also experienced remission.[20] This has been demonstrated in other studies as well. The fact that uSpA can spontaneously remit draws parallels with ReA, suggesting that some patients with uSpA might in fact have ReA with an asymptomatic or unrecognized triggering infection. Another analysis of SpA patients suggests that disease onset in individuals 40 years of age or younger are seen with predominance of axial symptoms, whereas those with later disease onset favor peripheral manifestations.[24]

**TABLE 76-1** Amor Criteria

| Clinical Symptoms or History | Points |
|---|---|
| Lumbar or dorsal pain during the night, or morning stiffness of lumbar or dorsal spine | 1 |
| Asymmetric oligoarthritis | 2 |
| Buttock pain<br>If affecting alternately the right or the left buttock | 1<br>2 |
| Sausage-like toe or digit (dactylitis)* | 2 |
| Heel pain or any other well-defined enthesopathy (enthesitis)* | 2 |
| Iritis | 2 |
| Nongonococcal urethritis or cervicitis accompanying, or within 1 month before, the onset of arthritis | 1 |
| Acute diarrhea accompanying, or within 1 month before, the onset of arthritis | 1 |
| Presence or history of psoriasis, balanitis, or inflammatory bowel disease (ulcerative colitis or Crohn's disease) | 2 |
| **Radiologic Finding**<br>Sacroiliitis (grade >2 if bilateral; grade >3 if unilateral) | 3 |
| **Genetic Background**<br>Presence of HLA-B27, or familial history of ankylosing spondylitis, Reiter syndrome, uveitis, psoriasis, or chronic enterocolopathies | 2 |
| **Response to Treatment**<br>Good response to NSAIDs in less than 48 hr, or relapse of the pain in less than 48 hr if NSAIDs discontinued | 2 |

*A patient is considered to have spondyloarthritis if the sum of the point counts is 6 or more. A total point count of 5 or more classifies for probable spondyloarthritis.

**TABLE 76-2** Calin Criteria for Inflammatory Back Pain*

| |
|---|
| Age at onset <40 years |
| Duration of pain >3 months |
| Insidious onset |
| Morning stiffness |
| Improvement with exercise |

*Requires the presence of 4/5 criteria

**TABLE 76-3** Berlin Criteria for Inflammatory Back Pain*

| |
|---|
| Morning stiffness of >30 minutes duration |
| Improvement in back pain with exercise but not rest |
| Nocturnal awakening (second half of the night only) |
| Alternating buttock pain |

*Sensitivity of 70% and specificity of 81% if two of the four criteria are fulfilled.

## GENETICS, PATHOGENESIS, AND ETIOLOGY

Because uSpA is poorly described, data regarding its etiology and pathogenesis are extremely limited. Although HLA-B27 is clearly associated with the risk of SpA, it is not the only contributory factor. In addition to HLA-B27, other genetic factors, including HLA-Cw*0602, HLA-B38,

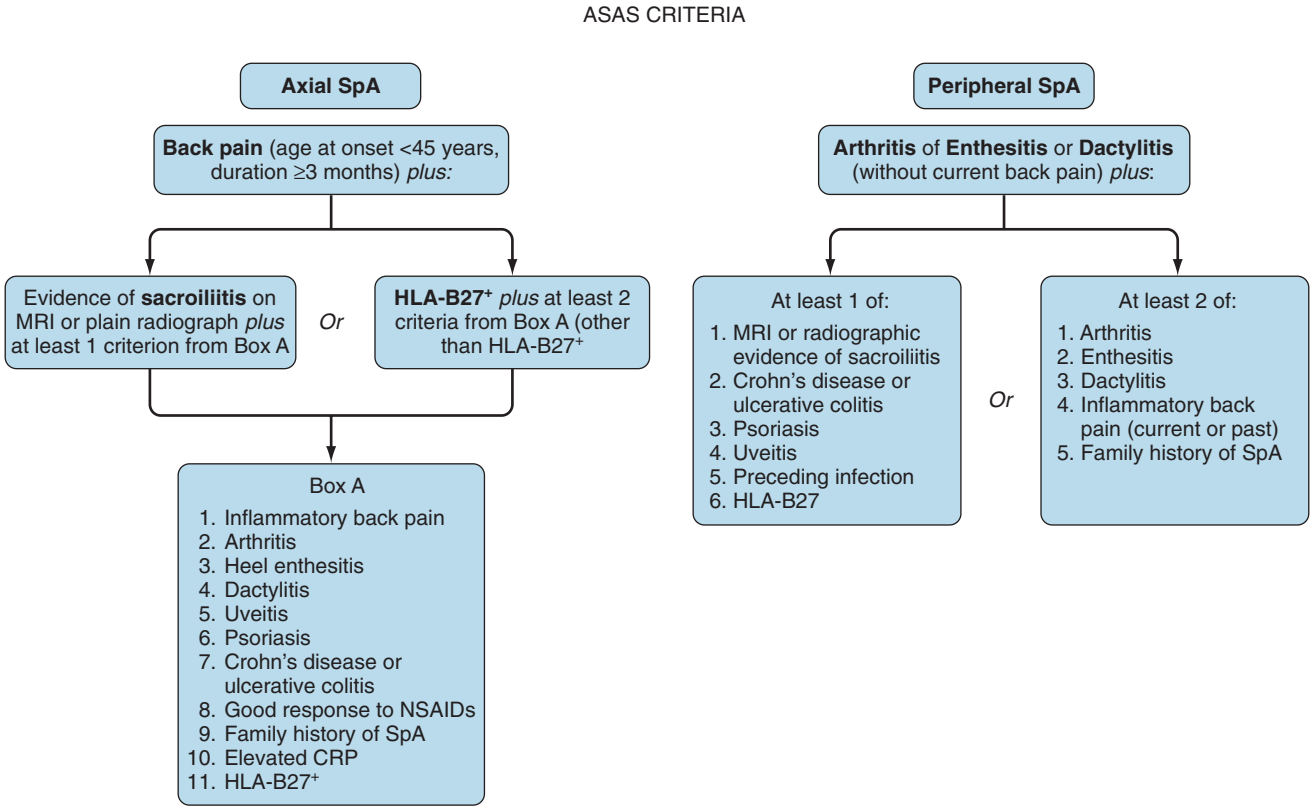

**Figure 76-2** The Assessment of SpondyloArthritis International Society (ASAS) classification criteria for axial and peripheral spondyloarthritis (SpA). To fulfill the criterion of sacroiliitis, the patient must have active (acute) inflammation on MRI highly suggestive of sacroiliitis associated with SpA or definite radiographic sacroiliitis according to the modified New York criteria. CRP, C-reactive protein; HLA, human leukocyte antigen; MRI, magnetic resonance imaging; NSAIDs, nonsteroidal anti-inflammatory drugs. *(From Zeidler H, Amor B: The Assessment in Spondyloarthritis International Society [ASAS] classification criteria for peripheral arthritis and for spondyloarthritis in general: the spondyloarthritis concept in progress.* Ann Rheum Dis *70:1–3, 2011; Rudwaleit M, Landewé R, van der Heijde D, et al: The development of Assessment of SpondyloArthritis International Society classification criteria for axial spondyloarthritis [part I]: classification of paper patients by expert opinion including uncertainty appraisal.* Ann Rheum Dis *68:770–776, 2009; and Rudwaleit M, van der Heijde D, Landewé R, et al: The development of Assessment of SpondyloArthritis International Society classification criteria for axial spondyloarthritis [part II]: validation and final selection.* Ann Rheum Dis *68:777–783, 2009.)*

HLA-B39, HLA-B60, HLA-DRB1, as well as those outside the major histocompatibility complex (e.g., ERAP-1 and IL-23R) have been associated with the SpAs in general. Because phenotypic congruity exists between SpA and uSpA, these genes likely play a role in uSpA as well. Approximately 50% to 70% of patients with uSpA are HLA-B27+.[25] The HLA-B*5703 allele was shown to be significantly increased in HIV+ individuals with uSpA in a Zambian population.[26] HLA-B60, HLA-C3, HLA-DR12, CXCR4, IL-1β, IL-8, and integrin-1 all also have been directly linked with uSpA.[27,28] Gene expression profiles in peripheral blood mononuclear cells from patients with AS and uSpA identified RGS1 as a candidate biomarker, especially for uSpA.[29]

Studies have been performed to investigate a potential bacterial trigger for uSpA. These studies have concentrated on the known triggers of ReA, and the resulting data have suggested potential causative links with chlamydiae and salmonellae.[30,31] However, DNA from a wide spectrum of bacterial species, including those known to be involved in ReA and others not previously associated with ReA, also have been detected in patients with uSpA. The pathogenic significance of these findings remains unclear.

## CLINICAL FEATURES

The clinical picture of uSpA is congruent with those of other forms of SpA. Most types of SpA begin around the ages of 15 to 45 years, including uSpA. However, like other types of SpA, uSpA can begin in childhood or later in life as well. Most individuals with uSpA lead long and productive lives, but certain complications can lead to disability. By the very definition of the condition, uSpA encompasses a host of symptoms that are shared in the SpA family without any unique or identifying characteristics. Although the various classification criteria are meant to facilitate clinical research and are not intended for clinical diagnosis, they are useful as a group to identify the various potential phenotypic features of uSpA. Channeling bias might lead to a diagnosis of uSpA in those who are seen with axial radiographic features versus those with only peripheral manifestations.

The clinical presentation of uSpA is dominated by inflammation that can affect the axial skeleton (spine and sacroiliac [SI] joints), peripheral joints (especially the large joints of the lower extremities), enthesitis, dactylitis, and extra-articular sites. Extra-articular manifestations are

heterogeneous and shared among all members of the SpA group; exceptions include mucocutaneous lesions in PsA and ReA, genitourinary manifestations in ReA, and the gastrointestinal manifestations in inflammatory bowel disease (IBD) and, possibly, AS. However, ocular and cardiac manifestations can be present in uSpA. Of uSpA patients, 20% to 30% experience mild intermittent abdominal symptoms or short episodes of diarrhea. Gut inflammation is mainly subclinical and can only be demonstrated by ileocolonoscopy.[32] In addition to genetic background and the possible role of environmental triggers, mechanical stress also appears to play a role in the articular features of uSpA. The male to female ratio of uSpA has been estimated to be 3:2.[25]

Recent data suggest that patients with uSpA are younger and tend to have shorter disease duration than those with AS or PsA.[33] These patients typically are seen with a mixed axial and peripheral arthritis, with the former dominating, and nearly half the patients have radiographic sacroiliitis.[33] Their overall disease activity tends to be similar to the other subtypes of SpA. Bone loss in the hip has been reported in patients with early uSpA and is related to disease activity.[34]

## LABORATORY, RADIOGRAPHIC, AND ADVANCED IMAGING FINDINGS

No specific laboratory findings have been described in patients with uSpA. Patients can be seen with elevated or normal acute phase reactants such as C-reactive protein (CRP) or erythrocyte sedimentation rate (ESR). Those that do have elevated acute phase reactants, however, tend to have poorer outcomes. The plain radiographic features of uSpA are similar to those of the other subtypes of SpA without unique features. Although radiographic sacroiliitis of AS- and IBD-related SpA tend to be bilateral and symmetric, the radiographic features in uSpA tend to be asymmetric and/or unilateral, as might be seen in PsA or ReA. Because many patients with uSpA have a short disease duration and can progress to a classic subtype of SpA (such as AS), recent efforts have been made to identify patients with "nonradiographic" axial spondyloarthritis, including uSpA. MRI of the SI joints can demonstrate synovitis and bone marrow edema (osteitis). These lesions can be detected months to years before the plain radiographic appearance of sacroiliitis. However, it should be noted that these MRI findings are highly suggestive but not unique to uSpA or the SpAs in general.

## DIAGNOSIS

No specific diagnostic test for uSpA currently exists. Patients are typically described as seronegative (i.e., absence of rheumatoid factor). However, uSpA and SpA in general are often quite easily distinguished from rheumatoid arthritis by the clinical presentation. Other helpful but nonspecific findings can include anemia of chronic disease and inflammatory synovial fluid (>2000 white blood cells/mL, with a predominance of neutrophils). As described previously, HLA-B27 testing is of limited value.

The newer ASAS classification criteria might be the most useful. The ASAS classification criteria for axial SpA are defined as follows: the presence of sacroiliitis by radiography or MRI, plus at least one SpA feature, or the presence of HLA-B27 plus at least two clinical features. The specificity of these criteria was higher than that of the ESSG modified for MRI and modified Amor criteria.[35] There are ASAS classification criteria for patients with peripheral manifestations only as well (see Figure 76-2).

## TREATMENT

Until recently, treatment options for patients with SpA have been limited. NSAIDs have been used as first-line drugs because they have been shown to help the symptoms of patients with SpA, especially when they are suffering from axial symptoms. TNF inhibitors have been studied extensively in patients with AS and PsA in recent years and have demonstrated excellent efficacy at treating the clinical symptoms of both conditions. These same medications have demonstrated radiographic protective effect on the peripheral joints of patients with PsA, but they appear to have little to no effect on the radiographic axial features of patients with SpA. Interestingly, large retrospective studies suggest an axial radiographic protective effect with NSAIDs in AS.[36] There appears to be a clear role for regular physiotherapy in AS to prevent loss of spinal mobility.

Far fewer data exist regarding treatments specifically effective for uSpA. As described previously, uSpA should not be considered a milder form of AS or other type of SpA. Data demonstrate comparable disease activity between uSpA and AS in terms of measures of disease activity, enthesitis, and uveitis.[37] Most treatment recommendations are extrapolated from AS and PsA studies. NSAIDs, cyclooxygenase (COX)-2 inhibitors, and disease-modifying antirheumatic drugs (DMARDs) are the main therapeutic agents used in uSpA, particularly those with peripheral manifestations. Of the DMARDs specifically, sulfasalazine or methotrexate are most often used. Sulfasalazine is the only traditional DMARD that has demonstrated potential efficacy in a prospective clinical trial in uSpA.[38] Local injections of corticosteroids can be effective in cases of monoarthritis or oligoarthritis, enthesitis, bursitis, or tenosynovitis.[39] In patients with axial involvement or severe manifestations despite conventional treatment, TNF inhibitors should be considered. TNF inhibitors effectively treat the clinical symptoms, decreasing acute phase reactants, and improving the MRI findings in patients with uSpA.[25]

CHAPTER 77

# Psoriatic Arthritis

Oliver FitzGerald • Musaab Elmamoun

## KEY POINTS

- Psoriatic arthritis should be suspected in a patient with an asymmetric joint distribution pattern who may have additional clinical features, such as dactylitis, enthesitis, or inflammatory-type back pain, and who is negative for rheumatoid factor.
- New classification criteria, the Classification of Psoriatic Arthritis (CASPAR) criteria, have been validated.
- Psoriatic arthritis is a progressive disease. Erosions develop in 47% of patients within 2 years of diagnosis. Polyarticular disease and an elevated erythrocyte sedimentation rate are markers of poor outcome.
- An essential core set of domains and instruments is necessary for inclusion in clinical trials.
- Studies of synovial tissue demonstrate increased vascularity and the presence of neutrophils, which might help distinguish spondyloarthropathy from rheumatoid arthritis. Change in synovial $CD3^+$ T cell synovial infiltration might be associated with clinical response to treatment.
- Prominent entheseal involvement with bone marrow edema at entheseal insertions on magnetic resonance imaging has prompted the hypothesis that psoriatic arthritis may originate at the enthesis.
- $CD8^+$ T cells and the innate immune response could participate in disease pathogenesis.
- Although there is a paucity of evidence for efficacy of disease-modifying anti-rheumatic drugs in psoriatic arthritis, TNF inhibitors have proved effective for skin and joint disease.

Psoriatic arthritis is a member of the spondyloarthropathy family and may be defined as an inflammatory arthropathy associated with psoriasis and usually negative for rheumatoid factor. Until the 1950s, an inflammatory arthritis that occurred in the presence of psoriasis was thought to represent rheumatoid arthritis (RA) occurring coincidentally with psoriasis. Based primarily on clinical and radiologic grounds and with use of the rheumatoid factor, the distinction between RA and psoriatic arthritis was gradually accepted. Wright described the classic clinical features in 1959, and with his colleague Moll, he published his classification criteria in 1973.[1,2] Until recently, these criteria have been the simplest and the most frequently used in clinical studies. The American Association of Rheumatism included psoriatic arthritis as a distinct clinical entity in the classification of rheumatic diseases for the first time in 1964.[3]

## EPIDEMIOLOGY

Epidemiologic studies have supported the concept that psoriatic arthritis is a unique disease entity separate from RA. The prevalence of inflammatory arthritis is increased among patients with psoriasis, ranging from 7% to 25% compared with a general population estimate of 2% to 3%. The prevalence of psoriasis among patients with arthritis also is increased, at a rate of 2.6% to 7% compared with a general population estimate of 0.1% to 2.8%.[4]

Psoriasis affects approximately 2% of the population. The prevalence varies: 5% to 10% of Russians and Norwegians are affected, but only 0% to 0.3% of West Africans or Native Americans are affected.[5] Onset of psoriasis may occur at any age, but it most frequently peaks in the twenties. Although no gender predilection has been reported, a genetic predisposition has been noted.

Among patients with psoriasis, arthritis develops in 7% to 42%. This figure varies widely in part because of a lack of widely accepted diagnostic criteria; it also varies according to which population is studied. The exact prevalence and incidence of psoriatic arthritis are unknown. The reported prevalence of psoriatic arthritis ranged from 0.056% to 0.28% in a large population-based study in the United States.[6] Cases were defined as patients who reported a "physician diagnosis" of psoriasis and psoriatic arthritis. Prevalence was calculated at 0.25% (95% confidence interval [CI], 0.18% to 0.31%). Kay and colleagues[7] did a prevalence study in northeast England to evaluate records from six general practices; 81 of 772 patients with psoriasis had inflammatory arthritis, with a prevalence of 0.28%. A study by Mease and colleagues[8] that looked at prevalence of rheumatologist-diagnosed psoriatic arthritis in patients with psoriasis in Europe/North American dermatology clinics found that almost a third of patients with psoriasis had psoriatic arthritis (of 949 patients evaluated, 285 [30%] had psoriatic arthritis).[8] The reported incidence of psoriatic arthritis has varied from 3 to 23 cases per 100,000. Data from Rochester, New York, have shown an incidence rate of 6.59 per 100,000, whereas in Finland, 16 new cases of psoriatic arthritis were identified in a population of 87,000, yielding a mean incidence rate of 23 per 100,000.[9,10] By using the Icelandic genealogy database, risk ratios (RRs) for the development of psoriatic arthritis in a sample that spanned five generations were estimated.[11] Results confirmed a strong and complex genetic component with a significant RR up to the fourth-degree relatives of psoriatic arthritis patients, as well as an important environmental contribution.

## CLINICAL FEATURES

Plaque psoriasis, or *psoriasis vulgaris*, is the most common skin phenotype in patients with psoriatic arthritis. Other patterns of skin involvement may be seen (Figure 77-1). Although arthritis usually develops in a setting of an established diagnosis of psoriasis, some patients may be unaware that they have psoriasis, or psoriasis may develop after the onset of arthritis in approximately 15% of cases.[12] In a clinical study, the incidence of development of arthritis in patients with psoriasis remained constant (74 per 1000 person-years), whereas the prevalence increased with time since diagnosis of psoriasis, reaching 20.5% after 30 years.[13] If a patient is first seen with the classic articular

manifestations of psoriatic arthritis but does not report psoriasis or the presence of a rash, the physician must examine the patient's skin carefully, including the scalp and nails, because psoriasis frequently lurks in such areas. Examples of nail dystrophic changes are shown in Figure 77-2.

Although a more recent U.S. study suggests that the prevalence of psoriatic arthritis among psoriasis patients increases with psoriasis severity,[6] in clinical practice, little relationship has been observed between severity of skin involvement and severity of arthritis. In one prospective study, only 35% of patients reported that their skin and joint components flared at the same time.[12] Other systemic features of joint inflammation are common in patients with psoriatic arthritis, including stiffness after rest and fatigue. In one study of fatigue, a number of factors, including disease activity, physical disability, pain, and psychological distress, contributed to fatigue, with comorbid fibromyalgia and hypertension further adding to the challenge.[14] Compared with other core outcome measures, fatigue has been found to be an independent outcome measure that is sensitive to change.[15]

Patients with psoriatic arthritis present with symptoms and signs of joint, entheseal, or spinal inflammation. The joints involved at presentation in 129 early psoriatic

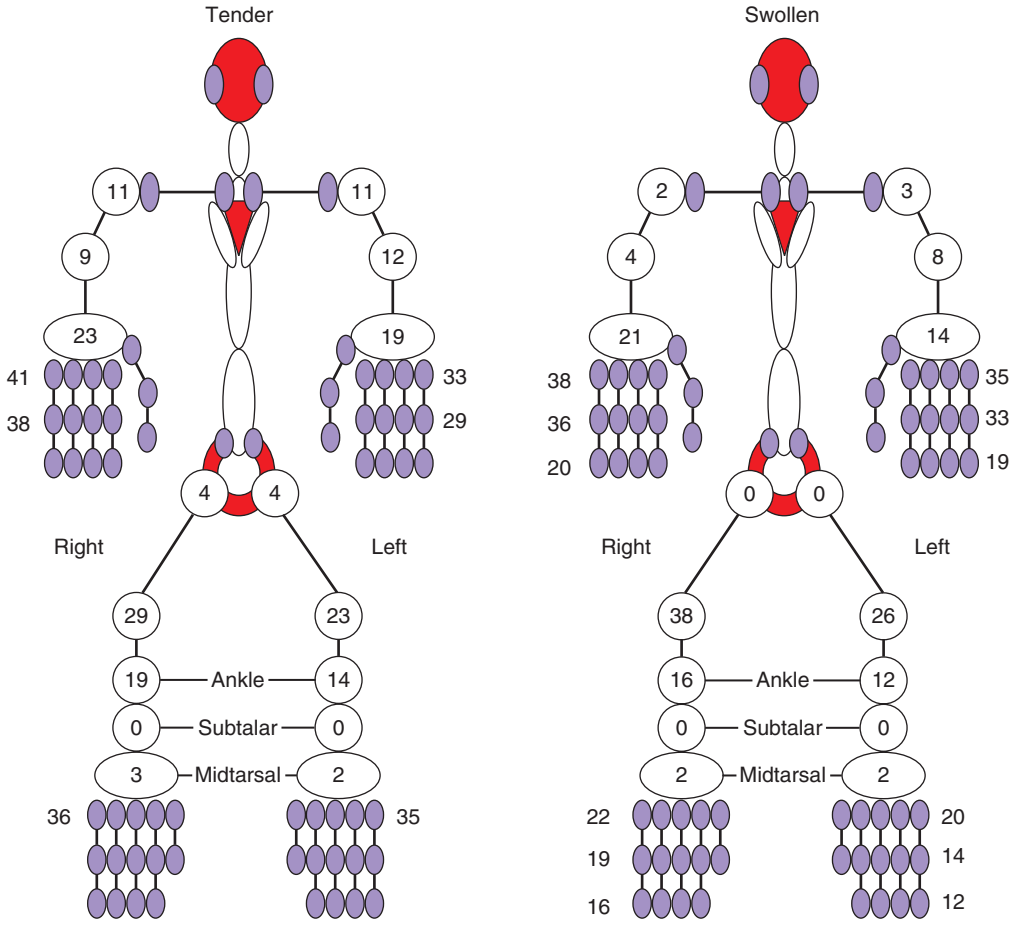

**Figure 77-3** Frequency (%) of peripheral limb joint involvement in 129 patients with early psoriatic arthritis as assessed by joint tenderness and swelling (distal interphalangeal joints of hand and proximal and distal interphalangeal joints of feet not assessed for tenderness as part of Ritchie Articular Index).

arthritis patients are shown in Figure 77-3. In one of their seminal papers on psoriatic arthritis, Wright and Moll[16] described five clinical patterns of psoriatic arthritis (Figure 77-4):

1. Asymmetric oligoarthritis
2. Symmetric polyarthritis
3. Predominant distal interphalangeal (DIP) joint involvement
4. Predominant spondyloarthritis
5. Destructive (mutilans) arthritis

These classification criteria are the most commonly quoted, although many alternative criteria have been proposed. Variability in the definition of terms has led to differences in the reported frequency of psoriatic arthritis in subsets among the different studies. The pattern of joint involvement is not fixed. The patient's disease may fluctuate and may be influenced by treatment. In a study of 129 patients with early psoriatic arthritis, 53 of 77 initially classified as polyarticular were reassessed at 2 years; 26 of 53 (49%) patients were subsequently classified as oligoarticular, 19 of 53 (36%) remained classified as polyarticular, and 12 of 53 (23%) were in remission.[17]

The Classification of Psoriatic Arthritis (CASPAR) study has included in the analysis a breakdown of disease pattern subtypes.[18] This multicenter study included data on 588 psoriatic arthritis cases and 536 controls. In contrast to the original Moll and Wright paper, but similar to many subsequent publications, approximately 63% of patients had polyarticular joint involvement, compared with 13% with oligoarticular disease. The other patterns of joint involvement described by Moll and Wright occurred much less commonly. Predominant DIP disease was found in less than 5%, but DIP involvement can occur in any of the subtypes. Predominant spondyloarthritis is uncommon, although spinal involvement may be found in 40% to 70% of psoriatic arthritis cases, depending on whether or not radiographs are taken.[19] Risk factors for spinal involvement include severe peripheral arthritis and human leukocyte antigen (HLA)-B27.[20] Finally, arthritis mutilans, a destructive form of arthritis associated with flail joints, is rare, although this form of joint involvement may develop in more patients with time if their disease is not properly controlled. The Group for Research and Assessment of Psoriasis and Psoriatic Arthritis (GRAPPA) has developed a broad consensus on the features of arthritis mutilans that include both clinical and radiologic features. The consensus was that the definition of arthritis mutilans should involve peripheral joints, especially of the hands and feet, but not axial joints. Involvement of one joint was considered sufficient. Rapidity of joint destruction was not considered

**Figure 77-4** Patterns of peripheral joint disease: asymmetric polyarticular disease. **A,** Distal interphalangeal joint involvement and forearm lymphedema. **B,** Toe dactylitis with skin and nail change. **C,** Predominant distal interphalangeal joint involvement. **D,** Arthritis mutilans.

important. Both clinical and radiographic features were important, but radiographic features were believed to be more sensitive. Clinical criteria include shortening of digits, digital telescoping, and/or flail joint not caused by subluxation. Radiographic criteria include erosion involving entire articular surfaces on both sides of the joint and/or pencil-in-cup change, osteolysis was considered to be the defining feature. Although ankylosis was a feature of severe joint destruction, it was placed into a different category distinct from arthritis mutilans.[21]

Features that are typical of psoriatic arthritis, including dactylitis and enthesitis, are helpful in diagnosis. Dactylitis, which is characterized by a sausage-shaped swelling of the fingers or toes (see Figure 77-4B), may be found in 29% to 33.5% of patients with psoriatic arthritis at first presentation, and 48% may have an episode of dactylitis during follow-up.[17,22] Ultrasound and magnetic resonance imaging (MRI) studies have shown that joint and tenosynovial inflammation are prominent in involved digits.[23,24] Enthesitis, inflammation at tendon and ligament insertion into bone, is a feature of all of the spondyloarthropathies and may be a presenting feature in psoriatic arthritis. Overall, enthesitis is found in 38% of patients at presentation.[17] The most common entheseal sites involved are the Achilles and plantar fascia insertions. Other sites include the insertions of the quadriceps and patellar tendons, the iliac crest, the rotator cuff, and the epicondyles at the elbow. Patients have reported pain at these sites, with tenderness and sometimes swelling noted on examination. Entheseal involvement may be asymptomatic, and ultrasound is more sensitive than clinical palpation. Often spurs are detected on radiograph, although spurs are not always associated with symptoms.

With the obvious exception of psoriasis and nail dystrophic change, extra-articular disease is less common in psoriatic arthritis than in RA. Iritis or uveitis occurs in 7% to 18%, more bilateral than in ankylosing spondylitis, but is usually found in patients with spinal involvement.[12,25] Numerous studies have suggested that patients with psoriatic arthritis have a higher prevalence of inflammatory bowel disease, sometimes asymptomatic and detected only on biopsy specimen.[26,27] Whether this inflammatory bowel disease is coincidental or is possibly related to medication effects remains to be clarified. Distal limb edema or lymphedema may occur more commonly in psoriatic arthritis; one case-control study found it in 21% of psoriatic arthritis patients compared with 4.9% of controls (see Figure 77-4A).[28] Finally, amyloid is rare but is described in psoriatic arthritis.

**TABLE 77-1** Clinical Features that Distinguish Psoriatic Arthritis from Rheumatoid Arthritis

| | Psoriatic Arthritis | Rheumatoid Arthritis |
|---|---|---|
| Psoriasis | + | – |
| Symmetric | + | ++ |
| Asymmetric | ++ | + |
| Enthesopathy | + | – |
| Dactylitis | + | – |
| Nail dystrophy | + | – |
| Human immunodeficiency virus association | + | – |

## DIFFERENTIAL DIAGNOSIS

Certain articular features, if present, are useful in distinguishing psoriatic arthritis from RA, including dactylitis, DIP involvement, and inflammation at entheseal sites (Table 77-1; see Figure 77-4). In addition, inflammatory-type back pain or sacroiliitis on plain radiograph or MRI should raise the suspicion of psoriatic arthritis because spinal involvement is uncommon in RA. The absence of rheumatoid nodules or other systemic features common to RA can be another useful differentiating feature.

Distinguishing psoriatic arthritis from other spondyloarthropathies is also important. Dactylitis may be a feature in reactive arthritis, in which a palmoplantar pustular rash (keratoderma blennorrhagicum) may be clinically and histologically indistinguishable from pustular psoriasis (see Figure 77-1G). In relation to spinal involvement, sacroiliitis may be unilateral more frequently, and the spinal changes on plain radiography may be more asymmetric in psoriatic arthritis than with classic ankylosing spondylitis. Finally, crystal-associated arthropathies occasionally can confuse, especially with monoarticular disease, and are best distinguished by synovial fluid crystal analysis. Serum urate levels may be increased in patients with psoriatic arthritis, adding to the confusion. To aid dermatologists and general physicians in identifying those with psoriatic arthritis, a number of screening tools for arthritis in patients with psoriasis have been proposed and are the subject of a current head-to-head comparative study.

## LABORATORY FEATURES

No diagnostic laboratory test for psoriatic arthritis is known. Although the absence of rheumatoid factor is considered an important distinguishing feature from RA, low levels of rheumatoid factor may be found in patients (5% to 16%) with typical psoriatic arthritis features. Until a more definitive diagnostic test becomes available, it is difficult to be categorical about diagnosis in these patients. Citrullinated protein antibodies (CPA) initially were thought to be specific to RA, but it is now recognized that CPAs are found in approximately 5% of patients with psoriatic arthritis as well.[29] Acute phase markers, such as erythrocyte sedimentation rate, C-reactive protein (CRP), and serum amyloid A, may be elevated in patients with psoriatic arthritis, but less commonly and to a lesser degree than in patients with RA. These markers are elevated in particular in patients with polyarticular disease, and act as a marker of poor prognosis.[30] Finally, as mentioned previously, hyperuricemia may be found in association with metabolic abnormalities in patients with psoriatic arthritis and may not reflect the extent of skin involvement.

## RADIOGRAPHIC FEATURES

Although substantial advances have been made in the application, in particular, of musculoskeletal ultrasound (MSUS) and of MRI in patients with arthritis, including psoriatic arthritis, plain radiographic imaging remains the "gold standard" for assessing bony changes in peripheral joints in psoriatic arthritis.

### Plain Radiography

Of patients with established psoriatic arthritis, 67% have radiographic abnormalities, 12% and 47% of patients with recent-onset psoriatic arthritis will have developed erosions within 2 years of disease onset.[17] Distinctive radiographic features reflect in some cases the clinical phenotype (Figure 77-5). These features include asymmetric joint involvement; involvement of the interphalangeal joints of the fingers and toes, with features of bony erosion and resorption sometimes seen together and resulting in the classic "pencil-in-cup" deformity; joint space narrowing or involvement of entheseal sites, often with bony spurs or development of periostitis; and spinal involvement, frequently less severe and asymmetric than in classic ankylosing spondylitis.

Radiographic progression in psoriatic arthritis is slow in early stages of the disorder, with the mean modified Sharp (to include DIP joints in the hands) erosion score at presentation increasing from 1.2 to 3 at 2 years.[17] Larson and Sharp scoring systems have been used in psoriatic arthritis, but neither the Larson nor the Sharp score has been developed specifically for psoriatic arthritis nor has it been extensively validated. Other scoring systems that have been proposed for use in psoriatic arthritis includes the modified sharp score (MSS), the Sharp/van der Heijde modified method (SHS), the modified Steinbrocker method, and the psoriatic arthritis Ratingen score. With the exception of the Ratingen method, these scoring methods were designed and validated for use in RA and subsequently modified for use in psoriatic arthritis. None of the existing radiographic measures are both sufficiently feasible and sensitive to change to be easily applied in large longitudinal observational studies.[31]

## MUSCULOSKELETAL ULTRASOUND

Many MSUS applications are useful in psoriatic arthritis; these applications are likely to develop further while the technology (in particular, power Doppler) that can be used to allow identification of blood flow is further advanced (Figure 77-6). It has already been shown that MSUS is more sensitive than clinical examination in detecting subclinical synovitis in early psoriatic arthritis—in this study, 96% of patients had at least one joint with subclinical

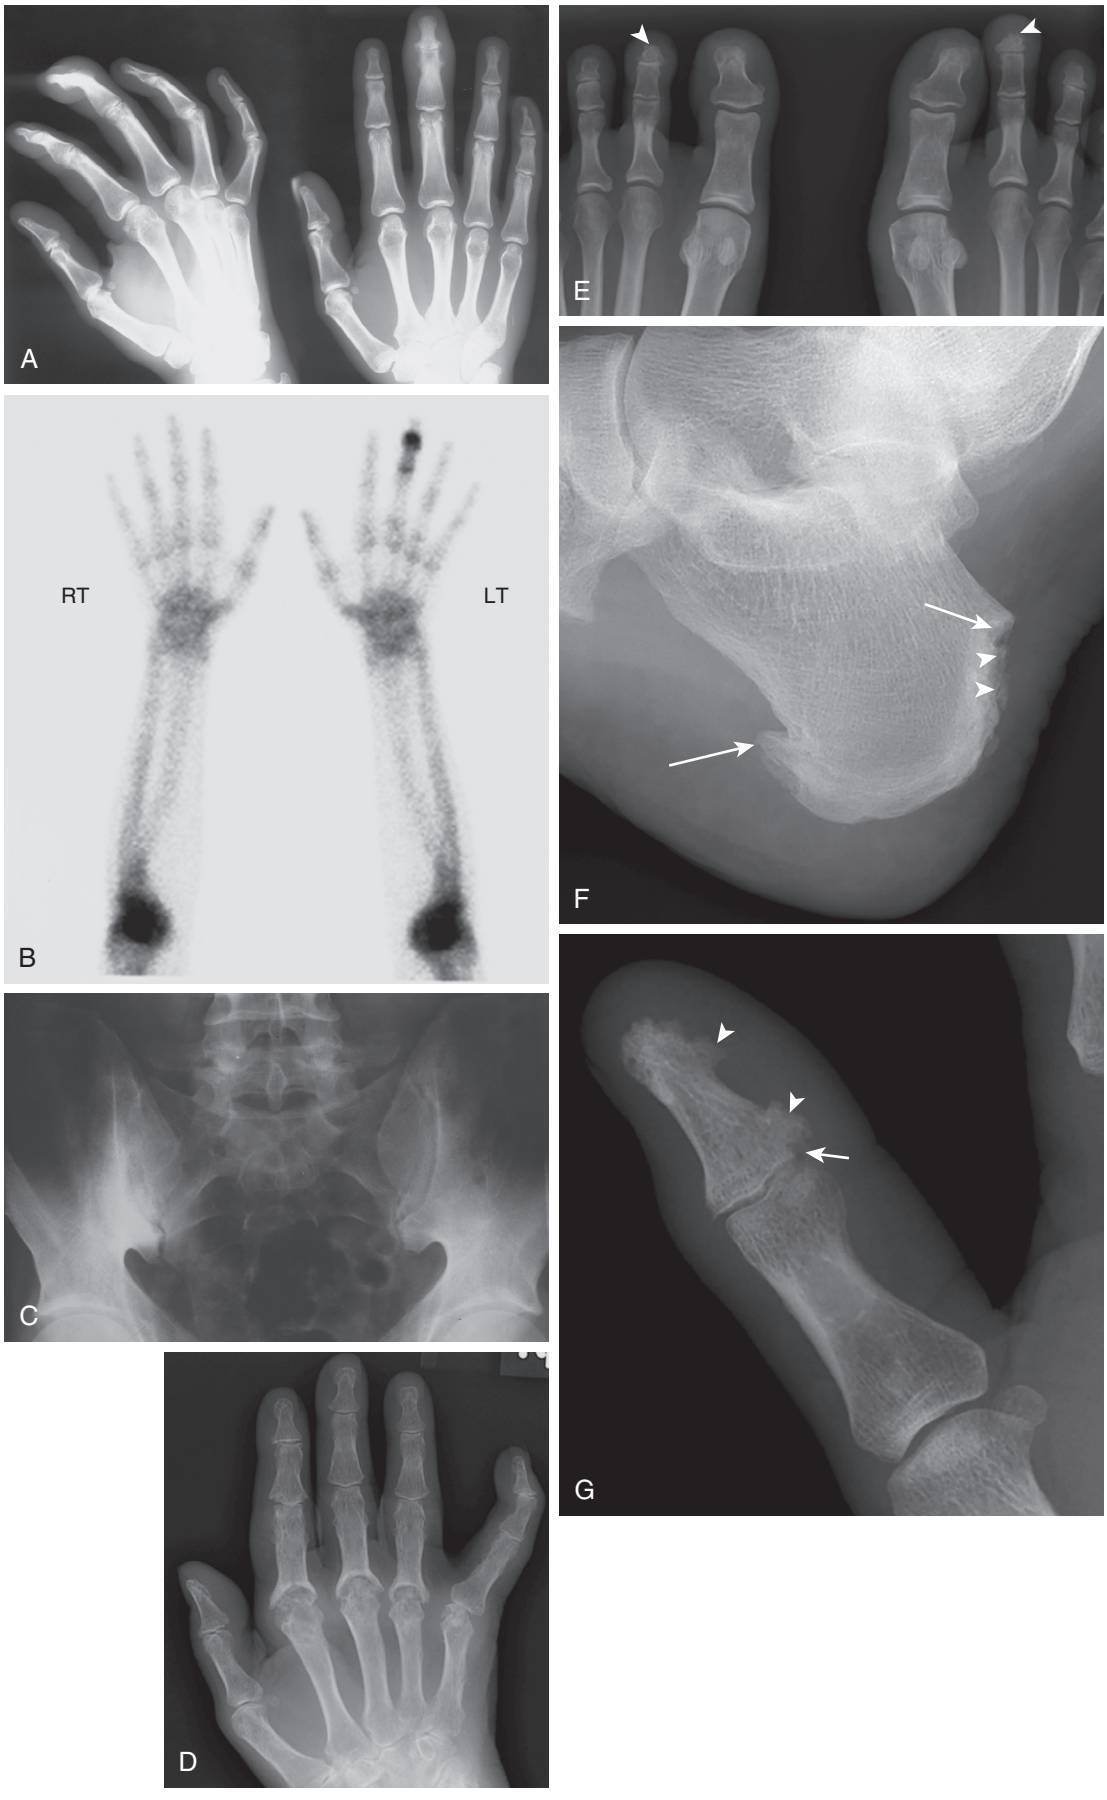

**Figure 77-5** Radiologic features in psoriatic arthritis. **A,** Third left distal interphalangeal joint monoarthritis with prominent new bone formation. **B,** Bone scan from same patient as in **A. C,** Asymmetric right-sided sacroiliitis. **D,** Arthritis mutilans. Severe destructive changes with multiple erosions and "pencil-in-cup" deformities. **E,** Acro-osteolysis. Destruction of the tufts of the distal phalanges of both second toes *(arrowheads)*. **F,** Enthesitis. Lateral view of the calcaneus shows a large erosion at the dorsal aspect of the calcaneus at the Achilles tendon insertion *(large arrow)*. There is some associated periosteal new bone formation *(arrowheads)*. A large plantar calcaneal spur is also demonstrated *(small arrow),* indicating enthesopathy at the plantar fascia origin. **G,** Periostitis. Radiograph of the thumb shows a marginal erosion of the base of the distal phalanx *(arrow),* with extensive cloaking of the surface of this phalanx with irregular periosteal new bone *(arrowheads)*. RT, Right; LT, left. *(Courtesy Dr. Robin Gibney and Dr. Eric Heffernan.)*

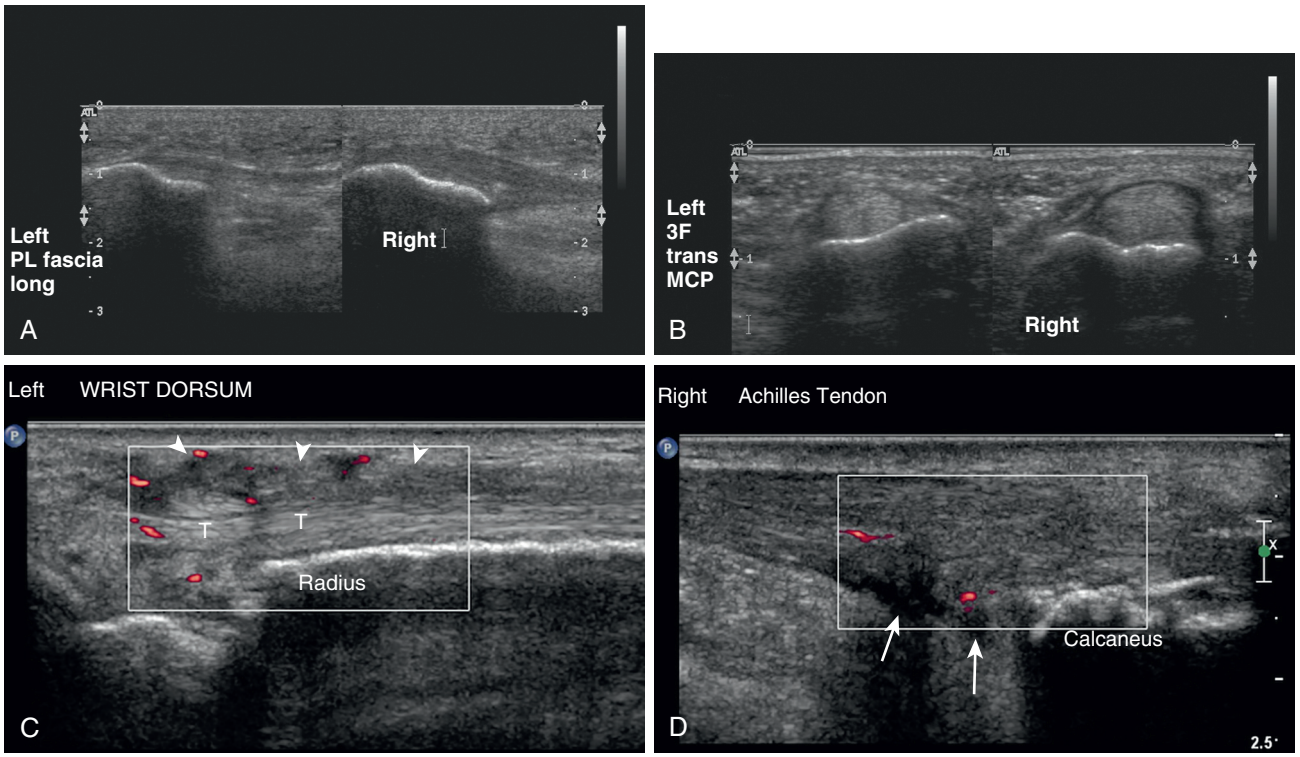

**Figure 77-6** Musculoskeletal ultrasound features in psoriatic arthritis. **A,** Right plantar fascia thickening compared with the left. **B,** Transverse section through left third finger at the metacarpophalangeal joint showing right tenosynovitis. **C,** Extensor tenosynovitis. Longitudinal ultrasound image of the dorsum of the wrist shows lobulated, hypoechoic thickening of the extensor tendon sheath *(arrowheads)* surrounding an extensor digitorum tendon *(T)*. Power Doppler has been used and shows hyperaemia *(red and orange pixels)* in the thickened tendon sheath. **D,** Retrocalcaneal bursitis and enthesitis. Longitudinal ultrasound image with Power Doppler shows hypoechoic thickening of the retrocalcaneal bursa *(arrows)*, deep to a severely thickened distal Achilles tendon. Abnormal color flow is demonstrated in the tendon, indicating neovascularization. There is also irregularity of the cortex of the calcaneus at the tendon insertion caused by erosions. *(Courtesy Dr. Robin Gibney and Dr. Eric Heffernan.)*

synovitis—and led to the majority of patients clinically diagnosed with oligoarthritis being reclassified with polyarthritis.[32] This reclassification may result in significant changes in prognosis and therapy. Finally, MSUS has been used in objective monitoring of the response of synovitis to therapy.[33]

MSUS features at the enthesis include entheseal thickening, hypoechoic change, increased vascularity as shown on power Doppler, tenosynovitis, and bony erosions or enthesophyte formation.[34,35] MSUS is a valid noninvasive tool, and it has been shown to be more sensitive than clinical examination in detecting lower limb enthesopathy. MSUS has also been shown to detect a high percentage of occult subclinical entheses abnormalities in patients with early psoriatic arthritis, independent of clinical examinations and symptoms.[35,36] MSUS has been used in studies of dactylitic digits. With MRI, MSUS has shown dactylitis to be caused by a combination of synovial and tenosynovial inflammation.[23,24] Finally, MSUS guidance for small joint or entheseal aspiration or injection may have particular application in patients with psoriatic arthritis.

## Magnetic Resonance Imaging

MRI studies have been particularly useful in offering new insights into disease pathogenesis in psoriatic arthritis. Based on the prominent entheseal-related bone marrow edema seen on MRI, McGonagle and colleagues[37] have proposed that psoriatic arthritis, in contrast to RA, is an entheseal-based disease. MRI can be used to study all aspects of joint involvement, including the enthesis, but use of MRI as a routine clinical tool in psoriatic arthritis has not been clarified. Application of MRI to the spine or sacroiliac joints in psoriatic arthritis may prove especially helpful, as has been shown in ankylosing spondylitis, especially in HLA-B27 related active axial psoriatic arthritis.[38] Preliminary studies have suggested that MRI can be useful as an outcome measure in the detection of synovitis or of vascularity in patients with psoriatic arthritis undergoing biologic therapies (Figure 77-7). More detailed studies are required. A new MRI scoring system has been proposed to measure articular inflammation and damage in patients with psoriatic arthritis (PsAMRIS).[39]

## Other Imaging Modalities

The use of other imaging modalities, such as computed tomography (CT) or scintigraphy, has largely been superseded by MRI. CT is now reserved mainly for patients for whom MRI is contraindicated, or for whom MRI is unavailable. Positron emission tomography (PET) has been found to be comparable with MSUS and MRI in the knees of patients with RA. An exploratory study used high-resolution [$^{18}$F] PET to explore the pattern of DIP joint bone metabolism in psoriatic arthritis compared with osteoarthritis and healthy joints. The authors conclude that this technique

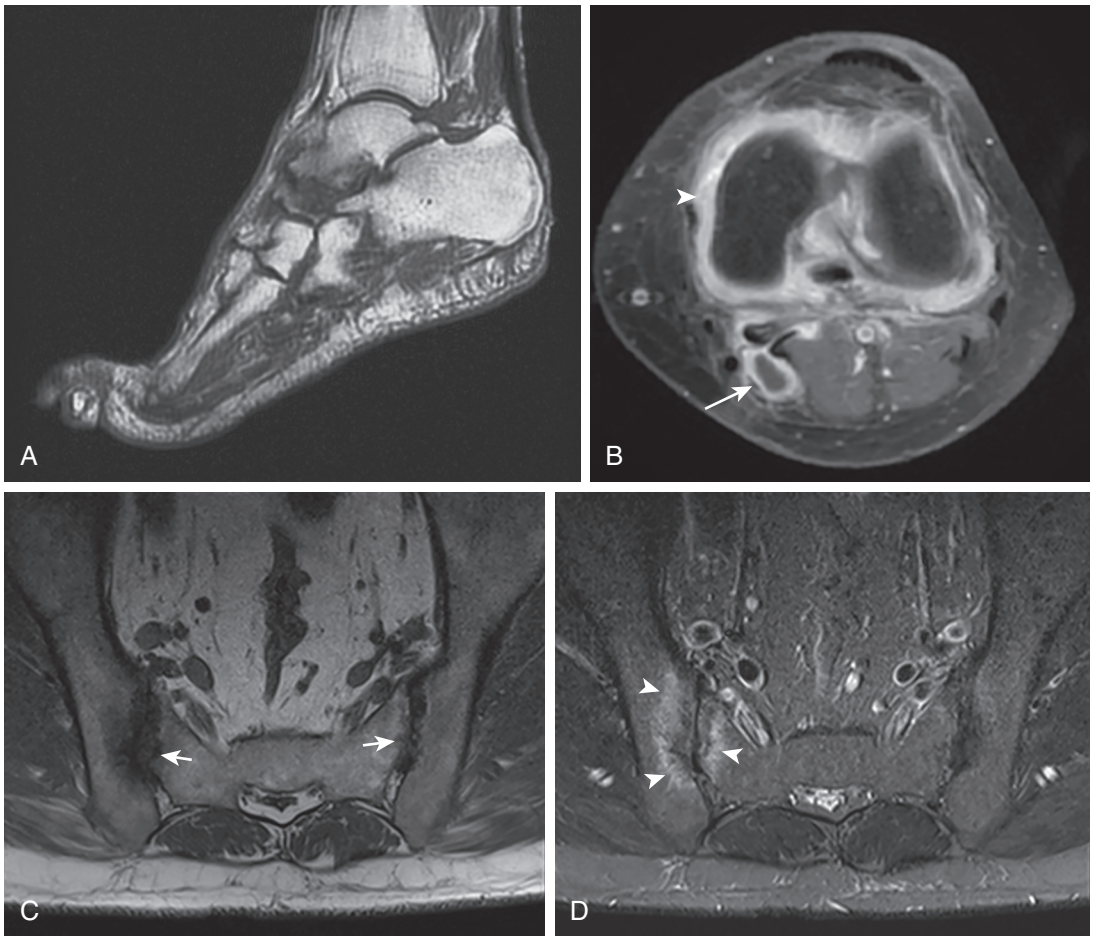

**Figure 77-7** **A,** T1-weighted magnetic resonance imaging (MRI) of left foot confirming severe talonavicular disease with bone edema. **B,** Knee synovitis. The synovitis extends to involve a small Baker's cyst in the popliteal fossa *(arrow)*. **C,** Asymmetric sacroiliitis. Transverse T1-weighted image shows low signal sclerosis around the right sacroiliac joint, in addition to bilateral erosions *(arrows)*. **D,** Transverse short tau inversion recovery image from same patient as in **C**, shows florid edema on both sides of the right sacroiliac joint *(arrowheads)*, with minimal edema on the *left*. *(Courtesy Dr. Robin Gibney and Dr. Eric Heffernan.)*

potentially offers a novel explanation for the known phenotypic expression of psoriatic arthritis and helps improve understanding of the bone-enthesis-nail complex.[40] In a study that used high-resolution CT imaging, structural bone changes were compared between patients with RA and patients with psoriatic arthritis. Smaller Ω-shaped and tubule-shaped erosions, as well as large, sometimes corona-shaped osteophytes, are typical of psoriatic arthritis. Another longitudinal study that described distribution, pattern, and development of erosions and proliferations in the hands of patients with hands by using high-resolution CT demonstrated that radiographs have low sensitivity, but high specificity for erosions and proliferations, when CT is considered the gold standard reference.[41]

## DIAGNOSIS

A diagnostic test for psoriatic arthritis is currently unavailable. Nevertheless, in its simplest form, psoriatic arthritis can be considered as an arthritis occurring in the presence of psoriasis, but in the absence of rheumatoid factor. Most patients with psoriatic arthritis meet this simple definition. The arthritis can be predominantly spinal, it may involve only entheseal sites, psoriasis may present after arthritis in 15% of cases, and low-titer positive rheumatoid factor may be found. Recognizing these difficulties, the CASPAR group published new classification criteria based on an analysis of 588 patients with psoriatic arthritis and 536 controls (Table 77-2). These criteria have now been well validated in a number of studies, both prospective and retrospective, with high sensitivity and specificity, including early psoriatic arthritis patients.[42] In the setting of clinical research, the CASPAR criteria have a specificity of 0.987 and a sensitivity of 0.914. For the individual patient, an algorithm for diagnosis is suggested in Figure 77-8.

## CLINICAL COURSE AND OUTCOME

Five early psoriatic arthritis cohorts have been studied.[17,43-46] The mean disease duration in these cohorts was 6 to 12 months, the median patient age at onset of psoriasis was 27 to 31 years, and the median patient age at onset of arthritis was 38 to 52 years. Overall, little relationship was noted between skin disease severity and onset of psoriatic arthritis.

**TABLE 77-2** CASPAR Classification Criteria for Psoriatic Arthritis

| |
|---|
| Inflammatory articular disease (joint, spine, or entheseal) with ≥3 points from the following: |
| 1. Evidence of psoriasis (one of a, b, or c)<br>a. Current psoriasis*: psoriatic skin or scalp disease present today as judged by a rheumatologist or dermatologist<br>b. Personal history of psoriasis: history of psoriasis that may be obtained from patient, family physician, dermatologist, rheumatologist, or other qualified health care provider<br>c. Family history of psoriasis: history of psoriasis in a first-degree or second-degree relative according to patient report |
| 2. Psoriatic nail dystrophy: typical psoriatic nail dystrophy, including onycholysis, pitting, and hyperkeratosis observed on current physical examination |
| 3. Negative test for rheumatoid factor: by any method except latex, but preferably by enzyme-linked immunosorbent assay or nephelometry, according to the local laboratory reference range |
| 4. Dactylitis (one of a or b)<br>a. Current swelling of an entire digit<br>b. History: history of dactylitis recorded by a rheumatologist |
| 5. Radiologic evidence of juxta-articular new bone formation: ill-defined ossification near joint margins (but excluding osteophyte formation) on plain radiographs of hand or foot |

Specificity 0.987, sensitivity 0.914 for CASPAR criteria.
*Current psoriasis scores 2, whereas all other items score 1.
CASPAR, Classification of Psoriatic Arthritis.

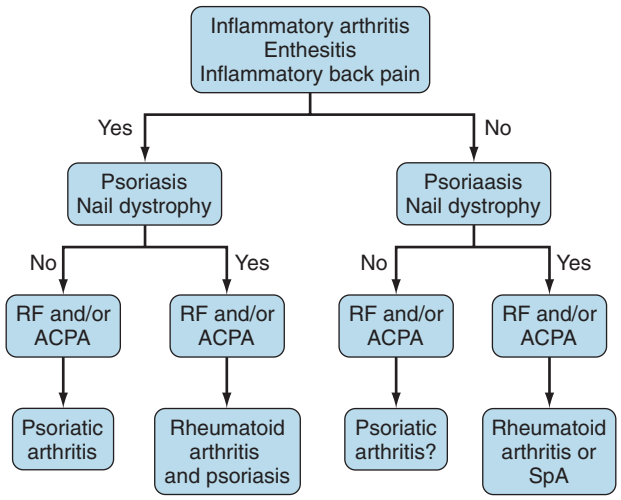

**Figure 77-8** Algorithm to be used in the diagnosis of individual patients presenting with possible psoriatic arthritis. Some patients may present with typical articular manifestations of psoriatic arthritis, but in the absence of skin or nail disease. They can be diagnosed as having definite psoriatic arthritis only when psoriasis subsequently develops. ACPA, Anti-citrullinated protein antibody; RF, rheumatoid factor; SpA, spondyloarthropathy.

The small joints of hands and feet were most commonly involved; the DIP joints were involved in one-third of patients, usually in association with nail disease, which was present in two thirds; dactylitis and enthesitis were present in one third; and spinal involvement only was found in 2% to 4%, but was present in 20% overall. At follow-up, disease had continued to progress in most patients. Erosive disease developed in 47% of patients within 2 years.[17] Markers for progression included polyarticular disease and an elevated erythrocyte sedimentation rate. Long-term follow-up studies have shown significant morbidity and increased mortality in psoriatic arthritis: 17% of patients have five or more deformed joints, 40% to 57% have a deforming arthritis, 20% to 40% have spinal involvement, 11% to 19% are disabled, and mortality is increased compared with the general population.[12,47,48]

## COMORBIDITIES IN PSORIATIC ARTHRITIS

Cardiovascular morbidity and mortality are increased in patients with psoriatic arthritis The risk of myocardial infarction, ischemic heart disease, hypertension, diabetes, and dyslipidemia was increased in cross-sectional and longitudinal prospective cohorts.[49] A number of studies have highlighted cardiovascular risk factors and the metabolic syndrome in psoriatic arthritis. In one study of 109 psoriatic arthritis patients compared with 699 RA and 122 ankylosing spondylitis controls, the adjusted odds ratio (OR) for the metabolic syndrome was 2.44 (1.48 to 4.01; $P < 0.001$) with adjusted ORs significantly increased for central obesity, impaired fasting glucose, and low high-density lipoprotein (HDL) cholesterol.[50] In another study of patients with psoriatic arthritis, 44% had metabolic syndrome ($n = 283$) and 16% had insulin resistance ($n = 263$). A significant association was also noted between metabolic syndrome and more severe psoriatic arthritis (OR 4.47, $P < 0.001$).[51] Psoriasis is associated with diabetes, independent of obesity and other traditional risk factors. Diabetes risk may also be elevated in psoriatic arthritis caused by systemic inflammation from both skin and articular disease. In a study that used a large U.K. general practice database, The Health Improvement Network (THIN), the authors evaluated the risk of incident diabetes among patients with psoriatic arthritis, psoriasis, and RA. They suggested that the overall risk of diabetes is increased in patients with psoriatic arthritis. Age- and sex-matched HRs for diabetes were 1.72 (95% CI, 1.46, 2.02) in psoriatic arthritis, 1.39 (95% CI, 1.32, 1.45) in psoriasis, and 1.12 (95% CI, 1.01, 1.25) in RA. After adjustment for BMI, smoking, alcohol, baseline glucocorticoid use, and co-morbidities, the HRs were 1.33 (1.09, 1.61) in psoriatic arthritis, 1.21 (1.15, 1.27) in psoriasis, and 0.94 (0.84, 1.06) in RA.[52] A large, population-based study by Ogdie and colleagues[53] used the same database to measure the risk of all-cause mortality among patients with psoriatic arthritis compared with the general population and with patients with psoriasis only and RA. It demonstrated an increased mortality in patients with severe psoriasis or RA but no statistically significant increase in mortality among patients with psoriatic arthritis. HR (age- and sex-adjusted) 1.02 (95% CI, 0.92 to 1.12), 1.56 (95% CI, 1.51 to 1.62), and 1.10 (95%, CI, 1.06 to 1.13) for psoriatic arthritis, RA, and psoriasis, respectively.

Surrogate markers of atherosclerosis were all unfavorable in psoriatic arthritis in terms of the increase in cardiovascular risk. Subclinical carotid artery atherosclerosis has been found to play a part in cardiovascular risk in patients with inflammatory arthritis. Several studies have assessed subclinical carotid atherosclerosis among patients with psoriatic arthritis by using carotid intima-media thickness (cIMT). cIMT appeared consistently greater in psoriasis and psoriatic arthritis compared with the general population.

Eder et al[49] compared the extent of subclinical atherosclerosis between patients with psoriatic arthritis and patients with psoriasis only. In the study, 125 patients with psoriatic arthritis and 114 patients with psoriasis were compared. Two surrogate measures of subclinical atherosclerosis were measured, cIMT and carotid total plaque area (TPA). The authors suggest that patients with psoriatic arthritis have more severe subclinical atherosclerosis, as reflected by higher carotid TPA, compared with psoriasis patients (TPA [square root of area in $mm^2$] 3.33 ± 3.34 vs. 2.43 ± 2.72, $P = 0.03$). The difference in cIMT between the groups did not achieve statistical significance.[49] Finally, a systematic review looking at cardiovascular comorbidities in psoriatic arthritis suggests an increased prevalence of cardiovascular disease in patients with psoriatic arthritis compared with the general population, as well as increased prevalence of cardiovascular risk factors.[54] It is important to note that when assessing cardiovascular disease and comorbidities, we must carefully discriminate between comorbidities associated with the psoriatic disease process itself versus those that are associated with and/or modified by co-existing cardiovascular risks and arthritis treatment. The European League Against Rheumatism (EULAR) has published evidence-based guidelines for cardiovascular risk management in patients with inflammatory arthritis.[55]

## OUTCOME DOMAINS AND INSTRUMENTS

Measuring response to treatment of psoriatic arthritis in clinical trials has been the subject of much interest for members of the GRAPPA and Outcome Measures in Rheumatoid Arthritis Clinical Trials (OMERACT). Many of the data that have been used to date in clinical trials have been adapted from RA and have not been validated. Controversial issues have included the number of joints to count, the usefulness of the acute-phase response in psoriatic arthritis, and how important it is to include a measure of function or quality of life in the trial. An essential core set of domains that must be included in clinical trials has now been agreed on, with other domains necessary but not mandatory, and still others that require considerably more research (Figure 77-9). Instruments for many of these domains have yet to be developed and validated, and some instruments, such as the Psoriasis Assessment Severity Index (PASI), have acknowledged limitations. Table 77-3 lists the currently available instruments for the core domains. Instruments for dactylitis and enthesitis have been proposed and validated.[56,57]

In the setting of clinical trials, numerous composite scores (e.g., American College of Rheumatology [ACR]20, ACR50, ACR70; EULAR Disease Activity Score [DAS] response criteria) have been used in psoriatic arthritis, most again adapted from RA and not extensively validated in psoriatic arthritis. One scoring system, the PsARC, was developed for psoriatic arthritis. Although it has been used in numerous studies, it has not been extensively validated and is considered perhaps insufficiently responsive and discriminant.[58] Much work is required to develop a validated and responsive composite instrument for psoriatic arthritis. A composite measure is one way of assessing all relevant clinical outcomes in a single instrument. Ideally, a composite index should combine practicability and feasibility with validity and clinical relevance. It should also provide a measure of disease activity, as well as response to therapy. Recently, minimal disease activity criteria (MDA) were developed and validated.[59] MDA provides an easy method to measure acceptable patient disease activity state. The definition of MDA was agreed at OMERACT as a state of disease activity deemed a useful target of treatment by both

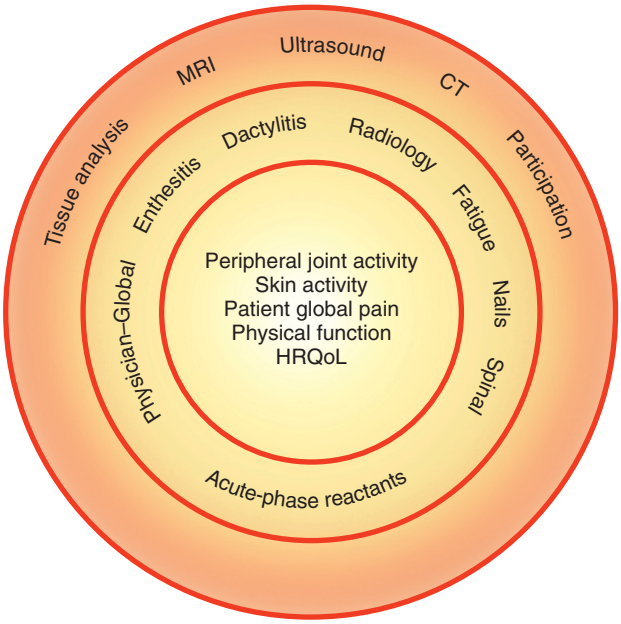

**Figure 77-9** Outcome domains in psoriatic arthritis. The central core domains are considered essential for inclusion in clinical trials. The middle circle contains domains that are considered important but not essential. The outer circle contains domains that all require further research and validation. CT, Computed tomography; HRQoL, health-related quality of life; MRI, magnetic resonance imaging.

**TABLE 77-3** Core Set Instruments Proposed for Use in Clinical Trials

| Domain | Instrument |
|---|---|
| Peripheral joint inflammation | Tender/swollen joint count 68/66 |
| Patient global assessment | Instrument under study* |
| Skin assessment | Psoriasis Assessment Severity Index (if body surface area ≥3%)<br>Lesion score (erythema, induration, scale)<br>Body surface area |
| Pain | Visual analogue scale or numeric rating scale |
| Physical function | HAQ/SF-36 physical function composite |
| Health-related quality of life | Generic disease specific (e.g., DLQI, PsAQoL) |

the patient and physician, given current treatment possibilities and limitations. MDA encompasses both remission and low disease activity as acceptable targets for therapy. It can be used as a responder index in addition to a target for treatment interventions. Patients with psoriatic arthritis are considered to have MDA when they meet 5 out 7 of the following criteria:

- Tender joint count ≤1
- Swollen joint count ≤1
- PASI ≤ 1, or body surface area (BSA) ≤3
- Patient pain, visual analogue scale (VAS) ≤15
- Patient global activity VAS ≤20
- Health Assessment Questionnaire (HAQ) ≤5
- Tender entheseal points ≤1

Two joint-related disease composite indices have been proposed. First, the Disease Activity Index for Psoriatic Arthritis (DAPSA), which is an adaptation of the Disease Activity index for Reactive Arthritis (DAREA), has been developed from a clinical cohort and validated using clinical trial data. DAPSA calculates the following components: tender joint count (0-68), swollen joint count (0-66), CRP level (mg/dl), patient VAS for pain (0-10), and patient VAS for global disease activity (0-10).[60] Second, a weighted articular responder index, the Psoriatic Arthritis Joint Activity Index (PsAJAI), a measure of response reflecting joint involvement in psoriatic arthritis, has been developed from randomized placebo-controlled trials of biologic agents in psoriatic arthritis.[61] The PsAJAI is a weighted sum of 30% improvement in core measures with weights of two given to joint count measure, CRP level, and the physician's global assessment of disease activity measure. Weights of one given to the remaining 30% improvement measures include pain, patient global assessment of disease activity, and the HAQ.

Three domain-based approaches have been proposed. First, the Composite Psoriatic Disease Activity Index (CPDAI) assesses as many as five domains: peripheral joints, skin, entheses, dactylitis, and spinal manifestations.[62] For each domain, instruments are used to assess both the extent of disease activity and the effect of involvement in that domain on patient function and health-related quality of life. Domains are scored 0 to 3, with empiric cutoffs for disease severity/activity proposed in each, largely based on the literature. Individual domain scores are summed to give an overall, composite score (range 0-15). This instrument has been validated in a large clinical trial data set, the Psoriasis Randomized Etanercept Study in Subjects with Psoriatic Arthritis (PRESTA). CPDAI better reflects all of the domains potentially involved in psoriatic arthritis. Unlike the DAPSA, this instrument could distinguish global treatment responses between two doses of etanercept in the PRESTA trial dataset. This suggests that the CPDAI is a more sensitive instrument to detect change in domains beyond joints and patient global, particularly in domains such as enthesitis, dactylitis, and skin that are important multidimensional components of psoriatic arthritis.[63] Second, the Grappa Composite Exercise (GRACE) project[64] derived two composite disease activity measures for psoriatic arthritis from a longitudinal study: the Psoriatic Arthritis Disease Activity Score (PASDAS) and Arithmetic Mean of Desirability Functions (AMDF). The PASDAS was developed by using linear regression and physician-defined cutoffs for disease activity. It is a weighted index incorporating patient and physician assessments of global disease activity, tender and swollen joint counts, dactylitis and enthesitis, the physical component of the Medical Outcome Study Short Form 36, and CRP. The AMDF (recently renamed the GRACE measure) is a composite index based on score transformations, incorporating measures of skin and joint involvement together with physical function; domains include tender joint count, swollen joint count, patient skin VAS, patient joint VAS, patient global VAS, HAQ, the Psoriatic Arthritis Quality of Life (PsAQoL) instrument, and PASI. Both instruments performed well and were able to distinguish active from inactive disease, but were less able to discriminate in subgroups of patients with oligoarthritis and patients with severe skin disease. A comparison of PASDAS, AMDF, CPDAI, and DAPSA was performed by using data from the GO-REVEAL study. This analysis allowed a comparison of their performance in a trial of a highly effective intervention. All indices were able to discriminate treatment from placebo. PASDAS, AMDF, and modified CPDAI better reflected domains such as skin, enthesitis, and dactylitis in addition to the articular component of the disease. The composite indices have demonstrated both face, content, and convergent validity and response to change; however, further testing of these indices in reliability studies is needed.[65] Finally, the questionnaire has been developed and validated in an international cross-sectional and longitudinal study in 13 countries. Two preliminary patient-derived weighted questionnaires to assess the impact of psoriatic arthritis on the patient's life were proposed. One questionnaire was for clinical trials and included nine domains, and the other was for clinical practice and included 12 domains. The domains included pain, fatigue, and skin problems, ability to work and participate in leisure activities, functional capacity, discomfort, sleep disturbance, coping, and anxiety. The domains of embarrassment and/or shame, social participation, and depression were added for the clinical practice questionnaire.[66]

## PATHOGENESIS

Many studies have explored key components of disease pathogenesis, including the contribution of genetic factors, the role of infection or trauma, studies of animal models or involved sites of disease, and the importance of components of the immune system, such as cytokines.

### Genetic Factors

Familial clustering of psoriasis and psoriatic arthritis is well described. Twin studies in psoriasis have shown a high rate of concordance in monozygotic twins.[67] The genetic basis for this clustering has been the subject of extensive investigations in psoriasis, but has been much less well studied in psoriatic arthritis. Studies of psoriatic arthritis have often included patients as a subset of larger psoriasis cohorts, and the diversity of clinical phenotypes has not often been recognized.

A strong association between psoriasis and the HLA-C region of the major histocompatibility complex (MHC) has long been recognized. Whether this was HLA-C*06 itself, found in approximately 60% of psoriasis cohorts, or a region

telomeric to this has been the subject of much controversy. Elder[68] definitively showed that the HLA susceptibility region for psoriasis is HLA-C*06, which is often in linkage disequilibrium with other HLA-B alleles such as HLA-B57, HLA-B37, and HLA-B13. The presence of HLA-C*06 is associated with an earlier patient age of onset of psoriasis (type 1 disease, <40 years old) and with more extensive and severe disease. Winchester et al,[69] confirmed by Eder et al,[70] have shown that in patients with psoriatic arthritis, the frequency of HLA-C*06 was lower than that in patients with psoriasis (28.7% vs. 57.5%; $P = 9.9 \times 10^{-12}$). Additional associations in psoriatic arthritis have been found with HLA-B27, HLA-B08, HLA-B38, and HLA-B39. It was also observed that arthritis develops much closer to the appearance of psoriasis in the HLA-B*27:05:02 or B*39:01:01 subset than in the HLA-C*06:02 subset of patients with psoriatic arthritis. Patients with B*27:05:02 had similar penetrance for musculoskeletal and skin disease, and they were roughly contemporaneous in onset; nearly a third of B*27:05:02 patients had the onset of skin disease after the onset of musculoskeletal disease, psoriatic arthritis sine psoriasis. Conversely for HLA-C*06:02 patients, the interval between skin disease and musculoskeletal disease was more than a decade, and the HLA-C*06:02 gene appeared to specify an effect that included highly penetrant severe cutaneous disease and delayed milder musculoskeletal disease with greatly reduced penetrance.

In a further exploratory study, HLA-B27 was also strongly associated with symmetrical sacroiliitis, enthesitis, and dactylitis. In contrast, HLA-B08 was associated with predominant asymmetrical sacroiliitis, joint fusion, joint deformities, and dactylitis. HLA-C06 was negatively associated with asymmetrical sacroiliitis.[71]

These findings have been interpreted to suggest that the MHC association with psoriasis lies close to the HLA-C region, whereas the MHC association with the articular manifestations more likely lies in or close to the HLA-B region. A study of a large cohort of patients with psoriatic arthritis in the United Kingdom found HLA-C*06 to be in linkage disequilibrium with HLA-DRBI*07, and that possession of both alleles was associated with fewer involved or damaged joints (Pauline Ho, personal communication, 2007).[72]

Other genes within the MHC region have been explored in psoriasis and psoriatic arthritis. Tumor necrosis factor (TNF) promoter polymorphisms or a gene in linkage disequilibrium with TNF may predispose the patient to or increase susceptibility to psoriasis and to psoriatic arthritis. One study has found a further association between the TNF-308 A allele and disease progression in early psoriatic arthritis.[73] Whole-genome scans in psoriasis have identified additional non-MHC susceptibility regions, known as the *PSORS regions* on chromosomes 4, 6, and 17. To date, no candidate genes have been identified.

Increasing evidence suggests that an additional or distinct genetic contribution is responsible for the development of psoriatic arthritis. Investigators have pointed to an class I MHC chain-related A (MICA)-A9 polymorphism, which confers additional relative risk, in particular for polyarticular disease, in patients with psoriasis who carry C*0602.[74] MICA-A9 polymorphism was found in linkage disequilibrium with HLA-B alleles (B*5701, B*3801). These results suggest that the *MICA* gene or other nearby genes may be involved in the development of psoriatic arthritis. Additionally, a genome scan identified a paternally influenced locus on chromosome 16—a region not known to be implicated in psoriasis susceptibility.[75]

Finally, two genome-wide association studies in psoriatic arthritis have been reported.[76,77] These studies have confirmed associations with HLA-C and interleukin (IL)-12B, and they have identified a new susceptibility region TRAF3IP2 on chromosome 6p, which encodes a protein involved in IL-17 signaling, and which interacts with members of the Rel/nuclear factor-κB (NF-κB) transcription factor family. Further studies[78] have provided genome-wide significant evidence for the involvement of the REL locus in psoriatic arthritis susceptibility, and confirmed the previously reported association with psoriasis vulgaris. A genome-wide significant association was found between psoriatic arthritis and a single-nucleotide polymorphism (SNP; rs13017599), detected at 2p16 near the REL locus encoding c-Rel (rs13017599, $P = 1.18 \times 10^{-8}$, OR, 1.27, 95% CI, 1.18-1.35).

## Environmental Factors

The role of environmental factors in triggering skin or joint disease in patients with psoriasis or psoriatic arthritis has been supported largely by clinical observations, although the mechanism is poorly understood. A strong association between guttate psoriasis and preceding streptococcal infections in children has long been recognized.[79] That this association might be related to a streptococcal superantigen has been proposed. Some authors have found bacterial antigens in synovial tissue samples from psoriatic arthritis patients, but this may be no different from those in non-inflammatory control participants.[80]

The Koebner phenomenon (see Figure 77-1H) has been reported to occur in 52% of patients with psoriasis. The Koebner phenomenon is the development of psoriasis along the site of skin trauma. It has been proposed that trauma may play a role in triggering episodes of joint inflammation, and the term *deep Koebner phenomenon* has been coined. Although the role of trauma has not been proved, in one study 24.6% of patients reported a traumatic event before the onset of arthritis.[81]

Finally, a link between stress and exacerbation of psoriasis has been proposed, supported largely by clinical observational studies. A similar association may exist in psoriatic arthritis, but this has not been systematically examined.

## Animal Models

Although spondyloarthropathy has been detected in a variety of primates, rodent models have proved helpful in deciphering pathogenic pathways. In rodents transgenic for class I HLA-B27 molecules, skin, nail, and joint features have been described that mimic some of the features of the human phenotype.[82] When HLA-B27 transgenic rats were raised in a germ-free environment, they seemed to be protected from joint disease. Mice genetically lacking class II MHC have developed skin and joint disease, but the disease is confined to the distal phalanges, with skin and nail disease also on the affected digits.[83] Involvement of the distal

phalanges and nails was reported in aging male DBA/1 mice from different litters that were caged together from 12 weeks.[84] In these animals, dactylitis, periostitis, and ankylosing enthesitis were observed.

Finally, JunB protein was shown to be expressed in healthy and in clinically uninvolved psoriatic skin, but expression was considerably reduced in involved psoriatic lesions.[85] Epidermal deletion of JunB and c-Jun in a mouse model resulted in skin and joint disease with 100% penetrance and a clinical and histologic phenotype highly consistent with human psoriasis and psoriatic arthritis. In further experiments, the same authors showed that the joint disease, but not the skin disease, required T and B cells and intact TNF receptor 1 signaling.

## Immunopathology

The key pathologic events in psoriatic arthritis occur in the skin, synovium, entheseal sites, and cartilage and bone. Pathobiologic features in the skin and synovium have been well described, but only a few studies have focused on the enthesis. In relation to cartilage and bone, studies have shown the presence of osteoclasts at the cartilage-pannus junction and high numbers of circulating osteoclast precursors in the circulation of psoriatic arthritis patients. Detailed studies similar to those done on RA on the synovial-cartilage-bone interface possibly could yield valuable information regarding joint destruction in psoriatic arthritis.

### Psoriasis Skin

Involved psoriasis skin is characterized by epidermal hyperplasia, mononuclear leukocytes in the papillary dermis, neutrophils in the stratum corneum, and an increase in various subsets of dendritic cells.[86] $CD8^+$ T cells are the predominant T cell subset chiefly found in the epidermis, whereas dermal T cells contain a mixture of $CD4^+$ and $CD8^+$. Most T cells in skin lesions express addressin, a cutaneous lymphocyte antigen, in contrast to circulating T cells and T cells found in the inflamed synovium in psoriatic arthritis.[87] Finally, vascular changes are prominent in psoriasis with impressive growth and dilation of superficial blood vessels.

### Psoriatic Synovium

Many early studies of synovial pathology in psoriatic arthritis highlighted the presence of prominent and striking vascular changes. In the first study that compared psoriatic arthritis and RA synovial tissue, quantitative immunopathologic analysis confirmed these prominent vascular changes and found that vessel number was significantly increased in psoriatic arthritis.[88] Lining layer hyperplasia was less marked in psoriatic arthritis, and fewer macrophages were seen trafficking into the synovium and out to the lining layer. The numbers of T lymphocytes and their subsets and the number of B cells were similar to the frequency found in RA. Although neutrophil infiltration was not assessed, this study examined adhesion molecule expression further in the two patient subgroups and found E-selectin expression to be considerably reduced in psoriatic arthritis. Many of these observations have been confirmed by other authors.

In a study by Kruithof and co-workers,[89] the synovial immunopathologic features in patients with spondyloarthropathy, including psoriatic arthritis, were compared with the features seen in RA.[89] Using a semiquantitative scoring system, the authors identified many features characteristic of the spondyloarthropathy group as a whole and in the psoriatic arthritis subgroup alone. Increased vascularity, higher neutrophil numbers (also seen in involved psoriasis skin), and a higher number of infiltrating $CD163^+$ macrophages, a marker of mature tissue macrophages, reliably distinguished spondyloarthropathy from RA. No significant differences were seen between oligoarticular versus polyarticular psoriatic arthritis.

The important role of the vasculature in psoriatic arthritis pathogenesis is perhaps most elegantly shown by the large numbers of tortuous and dilated blood vessels observed through an arthroscopic view of psoriatic joints.[90] An interaction of key growth factors is thought to regulate closely the new vessel formation or angiogenic process. Growth factors, including TNF, transforming growth factor (TGF)-β, platelet-derived growth factor (PDGF), angiopoietins (ANG-1, ANG-2), and vascular endothelial growth factor (VEGF), have been described in skin and synovial tissue.[91,92] Because this expression is found at an early stage of inflammation, it may represent a primary event in psoriatic arthritis versus a reaction or response to hypoxia. One possibility is that a genetic predisposition exists to endothelial activation, which results in new vessel formation and increased cellular trafficking.

Of interest, two studies have identified a change in synovial $CD3^+$ T cell infiltration as correlating with clinical response in patients commencing biologic therapies[93] (Pontifex, personal communication). Changes in CD3 infiltration also correlated with changes in MRI assessment of synovitis (Pontifex). Changes in CD3 infiltration may well prove to be a useful tissue biomarker of treatment response.

### Entheseal Sites

Laloux and associates[94] described the immunopathologic features of the enthesis in patients undergoing joint replacement surgery with spondyloarthropathy, including psoriatic arthritis, and compared them with RA. The number of patients was small in this study, but a consistent increase in $CD8^+$ T cell expression was observed at the enthesis in patients with psoriatic arthritis compared with RA patients. Ultrasound-guided biopsy of five sites of acute enthesitis in early spondyloarthropathy confirmed an inflammatory response with increased vascularity and cellular, predominantly macrophage, infiltration.[95] These findings are consistent with the well-described association of psoriatic arthritis with class I HLA antigens. They also are consistent with the previously described dominance of activated and mature $CD8^+$ T cells in psoriatic arthritis synovial fluid samples compared with RA.[96] It is attractive to suggest that enteseally derived antigens might trigger an immune response in adjacent synovial tissue. To date, evidence for this hypothesis has not been found, although this is clearly an area for future study. A search for candidate antigens common to the enthesis and the skin might be informative.

## Cytokines

Synovial explant tissues obtained from psoriatic arthritis joints have been shown to produce higher levels of the T helper (Th) type 1 cytokines IL-2 and interferon-γ protein than explants similarly cultured from osteoarthritis and RA patients.[97] This Th1 lymphocyte profile also has been observed in psoriasis plaques.[98] The cytokines IL-1β and TNF were released by psoriasis synovial explants in high concentrations. In contrast, IL-4 and IL-5 were not identified, but IL-10 was highly expressed in psoriatic synovium, although not in skin. A similar pattern of cytokine production in psoriatic arthritis synovium was shown by using immunohistochemical and gene expression techniques.[99,100] Other innate cytokines, such as IL-18 and IL-15, are present in psoriatic arthritis synovial tissue and are downregulated by methotrexate therapy.

The role of Th17 cells has been explored, and an important immunomodulatory role has been better established in psoriasis than in psoriatic arthritis. Comparison of lesional skin gene expression in responders versus nonresponders to etanercept revealed rapid downmodulation of innate IL-1β and IL-8 sepsis cascade cytokines in both groups, but only responders downregulated IL-17 pathway genes to baseline levels.[101] An increase in circulating Th17 cells has been found in psoriatic arthritis,[102] and an increase in IL-17 has been found in skin, synovial tissue, and synovial fluid of psoriatic arthritis patients.[103] Menon and co-workers demonstrated that IL-17$^+$CD4 T cells, consisting predominantly of CD8$^+$ T cells, are present at increased levels in psoriatic arthritis synovial fluid as compared with paired samples of psoriatic arthritis peripheral blood and synovial samples from patient with RA. In addition, the frequency of these synovial fluid IL-17$^+$CD4$^-$ T cells is correlated with serologic, clinical, and imaging measures of psoriatic arthritis disease activity and erosive disease status.[104] Further supporting a key role for the Th17 pathway, genetic polymorphisms in key cytokines involved in differentiation of T cells to Th1 and Th17 subtypes, IL-12 and IL-23, have been found to be associated with susceptibility to both psoriasis and psoriatic arthritis,[105] and inhibition of the common p40 subunit of IL-12/IL-23 has led to clinical improvement in both skin and joint manifestations.[106] Further observations by Benham et al[107] revealed a higher proportion of IL-17-producing cells within the peripheral blood mononuclear cells (PBMCs) of psoriatic arthritis and psoriasis patients compared with that of healthy controls (1.0% and 1.1% vs. 0.57%, respectively; $P$ <0.05, $P$ <0.01, respectively). The percentage of IL-22$^+$ CD4$^+$ T cells were also increased in PBMCs from patients with psoriatic arthritis compared with those of healthy controls (0.95% vs. 0.51%; $P$ <0.05), but the percentage increase in psoriasis patients relative to controls (0.81% vs. 0.51%; $P$ >0.05) was not statistically significant. There was no difference in the frequency of IL-17$^+$ and IL-22$^+$CD4$^+$ T cells between patients with psoriasis alone and those with psoriatic arthritis. In patients with psoriatic arthritis, CCR6$^+$ and IL-23R$^+$ T cell numbers were elevated in synovial fluid compared with peripheral blood. In addition to genetic associations described above, there are now substantial data implicating Th17-Th22-IL-23 axis in mouse models of both psoriasis and spondyloarthropathy; Sherlock and colleagues[108] have shown that the anatomic sites that are inflamed in spondyloarthropathy are primed to rapidly react to IL-23 by the presence of a previously unidentified population of IL-23R$^+$ resident cells and also in vivo exposure to IL-23 is sufficient to induce highly specific entheseal inflammation in the absence of Th17 cells and with rapid kinetics. The previous observations strengthen the case for the central involvement of the Th17-Th22-IL-23 axis in both psoriasis and psoriatic arthritis.

TNF levels are elevated in psoriatic skin, synovium, and joint fluid of patients with psoriatic arthritis.[97,109] Several lines of evidence support the concept that TNF is an important cytokine in the psoriatic joint. TNF transgenic mice exhibit extensive bone destruction similar to that observed in some psoriatic arthritis patients. In a study of 129 patients with early psoriatic arthritis, patients with erosions were significantly more likely to have the TNF-308 A allele, an allele associated with high TNF production.[73] As mentioned earlier, immunohistochemical and gene expression studies have shown marked upregulation of TNF in the psoriatic synovial membrane. Histopathologic analysis of synovial specimens from eight spondyloarthropathy patients, four of whom had psoriatic arthritis, treated with the anti-TNF monoclonal antibody infliximab revealed decreased vascularity, synovial lining thickness, and mononuclear cell infiltration after therapy.[110,111] In another study, a significant reduction in the quantity of infiltrating macrophages, the CD31$^+$ vascular area, αvβ3$^+$ neovessels/Ulex europaeus agglutinin–positive vessels, VEGF and its receptor KDR/flk-1 (VEGFR-2), and SDF-1–positive vessels in psoriatic arthritis synovium was noted after 8 weeks (three infusions) of infliximab treatment.[112]

## Matrix Metalloproteinases and Cartilage Destruction

Radiographs of psoriatic joints often reveal cartilage loss manifested as joint space narrowing. Similar to RA, matrix metalloproteinases (MMPs) and tissue inhibitors of MMPs (TIMPs) were identified in psoriatic arthritis synovial lining and sublining layers.[113,114] In particular, immunohistochemical studies revealed that MMP-9 localized to blood vessel walls, whereas MMP-1, MMP-2, MMP-3, TIMP-1, and TIMP-2 showed a cellular and interstitial staining pattern in the synovial lining. Serum levels of MMP-3 exhibited a marked and rapid decrease after successful anti-TNF therapy, raising the possibility that this molecule may serve as a biomarker. In another study, similar levels of MMP-1 and MMP-3 mRNA were detected in RA and psoriatic arthritis synovial tissue despite the fact that RA patients exhibited more erosions on plain radiographs.[115] The elevated ratio of MMPs to TIMP-1 in synovial tissue favored cartilage degradation, although expression of MMPs was not significantly elevated at the cartilage-pannus junction compared with other sites. These reports indicate that MMPs are upregulated in psoriatic arthritis synovium, but their precise functions remain to be defined.

## Bone Remodeling

Radiographs of psoriatic arthritis joints can reveal markedly altered bone remodeling in the form of bone resorption (tuft resorption or osteolysis, large eccentric erosions, and

pencil-in-cup deformities) and new bone formation (periostitis, spur or enthesophyte formation, bony ankylosis). Important in bone resorption, psoriatic joint biopsy specimens show large multinucleated osteoclasts in deep resorption pits at the bone-pannus junction.[116] Osteoclastogenesis (differentiation of monocytes into osteoclasts) is a contact-dependent process directed by osteoblasts and stromal cells in the bone marrow. These cells release signals necessary for differentiation of an osteoclast precursor derived from the $CD14^+$ monocyte population into an osteoclast.

One of these signals is the receptor activator of NF-κB ligand (RANKL), a member of the TNF superfamily that binds to receptor activator of NF-κB (RANK) on the surface of osteoclast precursors and osteoclasts. This ligand-receptor interaction stimulates proliferation and differentiation of osteoclast precursors and activation of osteoclasts. It has been proposed that the relative expression of RANKL and of its natural antagonist osteoprotegerin (OPG) ultimately controls osteoclastogenesis. In psoriatic arthritis synovial tissues, marked upregulation of RANKL protein and low expression of osteoprotegerin were detected in the adjacent synovial lining.[116] Osteoclasts also were noted in cutting cones traversing the subchondral bone, supporting a bidirectional attack on the bone in psoriatic joints. In addition, osteoclast precursors, derived from circulating $CD14^+$ monocytes, were markedly elevated in the peripheral blood of patients with psoriatic arthritis compared with healthy controls. Treatment of patients with psoriatic arthritis with anti-TNF agents significantly decreased the level of circulating osteoclast precursor, supporting a central role for TNF in the generation of this precursor population. Although abundantly expressed, there appeared to be little relationship between expression of RANKL, OPG, and RANK and both systemic and local inflammation,[117] and also little relationship between the decline in osteoclast precursor numbers and bone marrow edema following etanercept treatment.[118]

The mechanisms responsible for new bone formation in the psoriatic joint are poorly understood. Higher circulating levels of bone formation markers, in particular bone alkaline phosphatase, in patients with psoriatic arthritis compared with patients with RA both before and after TNF inhibitor therapy has been demonstrated (Szentepetery, personal communication). TGF-β and VEGF may be pivotal in this process of new bone formation, given that TGF-β is strongly expressed in synovial tissues isolated from patients with ankylosing spondylitis and synergizes with VEGF to induce bone formation in animal models.[119] De Klerck and colleagues[120] showed that the bone morphogenetic proteins (BMPs) BMP-2 and BMP-7 are upregulated in regions of pathologic new bone formation. These investigators showed that expression of phosphorylated Smad-1 and Smad-5, important signaling molecules downstream of BMP, was markedly increased in regions of new bone formation taken from the calcaneus in a patient with Achilles tendinitis and periostitis. These studies provide evidence that potential mediators of ankylosis and periostitis in the psoriatic enthesis and joint include BMP molecules and possibly VEGF and TGF-β. Finally, the Wnt pathway and the balance between Wnt and the Wnt antagonist dickkopf-1 (DKK-1), which binds to the Wnt receptor complex on the surfaces of osteoblast lineage cells, may well be of considerable importance in the disordered bone remodeling found in psoriatic arthritis.

## CONCLUSION

In considering a model for disease pathogenesis in psoriatic arthritis, we have to take into account genetic susceptibility, the role of the environment, cellular immunologic mechanisms, secreted cytokines, chemokines, and other proteins. For some time, the primary hypothesis has been that psoriatic arthritis is an class I HLA-restricted, antigen-driven immune process (Figure 77-10). Considerable evidence has been presented to support this hypothesis; however, despite careful analysis of T cell-receptor phenotype, no antigen-driven process other than that driven by Epstein-Barr virus has been identified.[121] The potential role of components of the innate immune response, such as Toll-like receptors or cells bearing natural killer receptors, is currently under active investigation. It is possible that the interaction of environmental factors, such as those derived from pathogens or expressed after trauma, with Toll-like receptors in a genetically susceptible individual, may set in motion intra-cellular signaling events that lead to cytokine release, immune activation, and release of destructive enzymes such as MMPs (Figure 77-11).

## TREATMENT

In considering treatment strategies for psoriatic arthritis, the diverse nature of the clinical phenotype (peripheral arthritis, skin and nail disease, axial disease, dactylitis, and enthesitis) may complicate therapeutic decisions because not all treatments are effective for all features, and patients often display a mixture of all of the features simultaneously. EULAR has published recommendations for the treatment of psoriatic arthritis based on a systematic literature review. The reader is referred to this publication for a detailed review of the evidence (Table 77-4; Figure 77-12).[122] Treatment choices may be driven by the disease feature considered most severe at the time of evaluation. Finally, in reviewing the evidence for therapeutic effect presented in the following section, recommendations from the Agency for Health Care Policy and Research were used, wherein interventions are scored by categories of evidence (level 1 through 4) and strength of recommendation (grade A through D).[123]

### Traditional Agents

Although little published evidence exists of a favorable therapeutic effect in psoriatic arthritis, nonsteroidal anti-inflammatory drugs are most often the agents first used in psoriatic arthritis, whatever the clinical phenotype (level 1b, grade A).[124] Expert opinion supports the use of nonsteroidal anti-inflammatory drugs, although occasional exacerbations of psoriasis have been reported. The use of systemic corticosteroids is not evidence based (level 4, grade D), although 24% of patients in one study were taking prednisolone.[125] Concerns have arisen suggesting that exacerbations of psoriasis may follow corticosteroid withdrawal. No randomized controlled trials have examined intra-articular steroids in psoriatic arthritis or the use of local entheseal or

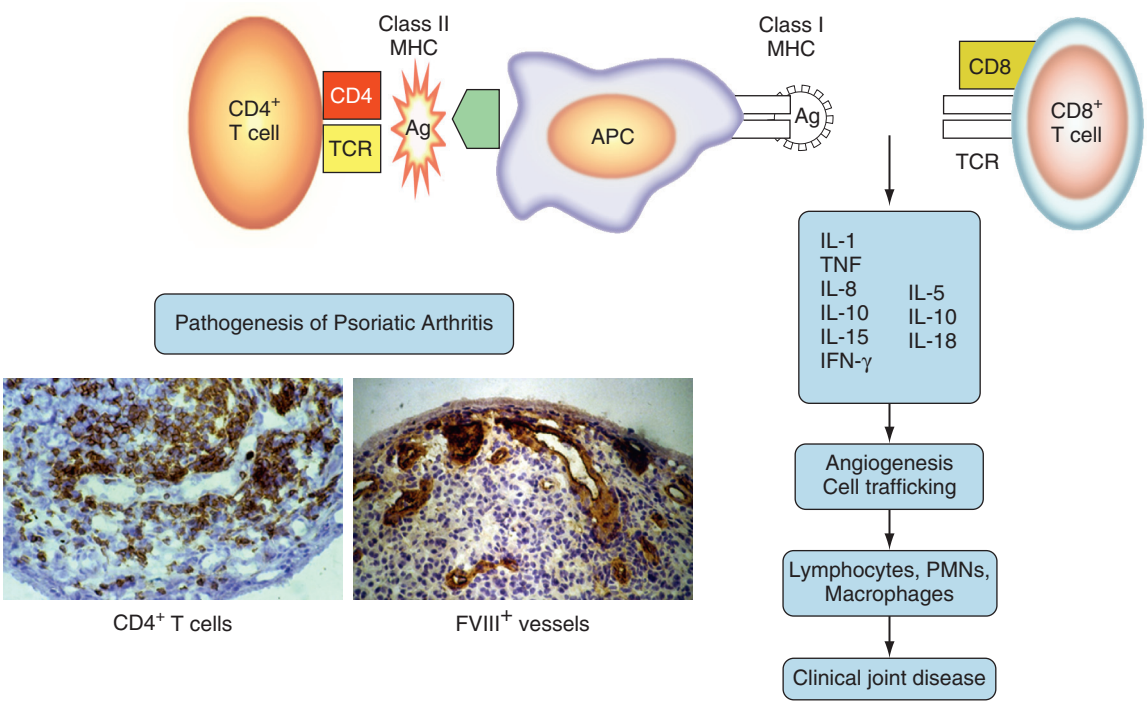

**Figure 77-10** Traditional disease pathogenesis model in psoriatic arthritis. APC, Antigen-presenting cell; FVIII, factor VIII; IFN, interferon; IL, interleukin; MHC, major histocompatibility complex; PMNs, polymorphonuclear neutrophils; TCR, T cell receptor; TNF, tumor necrosis factor.

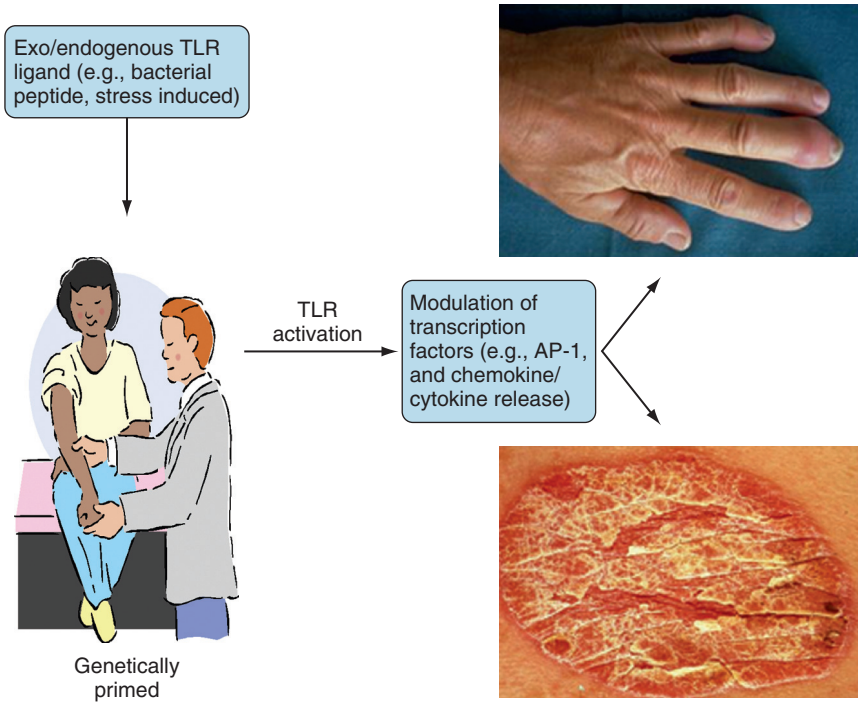

**Figure 77-11** Alternative model incorporating new disease pathogenesis concepts. TLR, Toll-like receptor.

dactylitis injections. Expert opinion indicates that intra-articular steroids can be quite effective, especially in oligoarticular disease, or where localized entheseal involvement is present, as in plantar fasciitis (level 4, grade D). Mild skin disease (PASI <10) is usually controlled with topical steroids or vitamin D derivatives; the latter are best used for maintenance therapy.[126]

Systemic therapy is considered in patients with three or more inflamed joints despite conventional therapy, as described previously; persistent or treatment-resistant axial, entheseal, or dactylitic disease, especially in which multiple sites are involved; or moderate or severe psoriasis (PASI >10). Randomized controlled trials of disease-modifying antirheumatic drugs (DMARDs) are few and limited by size.

**TABLE 77-4** Updated EULAR Recommendations for the Management of PsA with Levels of Evidence, Grade of Recommendations, and Level of Agreement

| | Overarching principles | Level of agreement (mean ± SD) |
|---|---|---|
| A. | PsA is a heterogeneous and potentially severe disease, which may require multidisciplinary treatment. | 9.6 ± 1.1 |
| B. | Treatment of patients with PsA should aim at the best care and must be based on a shared decision between the patient and the rheumatologist, considering efficacy, safety, and costs. | 9.2 ± 1.7 |
| C. | Rheumatologists are the specialists who should primarily care for the musculoskeletal manifestations of patients with PsA; in the presence of clinically significant skin involvement, a rheumatologist and a dermatologist should collaborate in diagnosis and management. | 9.5 ± 0.8 |
| D. | The primary goal of treating patients with PsA is to maximize health-related quality of life through control of symptoms, prevention of structural damage, normalization of function and social participation; abrogation of inflammation is an important component to achieve these goals. | 9.6 ± 1.0 |
| E. | When managing patients with PsA, extra-articular manifestations, metabolic syndrome, cardiovascular disease, and other comorbidities should be taken into account. | 9.5 ± 1.0 |

| | Recommendations | Level of evidence | Grade of recommendation | Level of agreement (mean ± SD) |
|---|---|---|---|---|
| 1. | Treatment should be aimed at reaching the target of remission or, alternatively, minimal/low disease activity, by regular monitoring and appropriate adjustment of therapy. | 1b | A | 9.6 ± 0.9 |
| 2. | In patients with PsA, NSAIDs may be used to relieve musculoskeletal signs and symptoms. | 1b | A | 9.6 ± 0.8 |
| 3. | In patients with peripheral arthritis, particularly in those with many swollen joints, structural damage in the presence of inflammation, high ESR/CRP, and/or clinically relevant extra-articular manifestations,[a] csDMARDs should be considered[b] at an early stage,[a] with methotrexate preferred in those with relevant skin involvement.[b] | [a]: 3<br>[b]: 1b | B | 9.4 ± 0.8 |
| 4. | Local injections of glucocorticoids should be considered as adjunctive therapy in PsA[a]; systemic glucocorticoids may be used with caution at the lowest effective dose.[b] | [a]: 3b<br>[b]: 4 | C | 9.1 ± 1.2 |
| 5. | In patients with peripheral arthritis and an inadequate response to at least one csDMARD, therapy with a bDMARD, usually a TNF inhibitor, should be commenced. | 1b | B | 9.5 ± 0.7 |
| 6. | In patients with peripheral arthritis and an inadequate response to at least one csDMARD in whom TNF inhibitors are not appropriate, bDMARDs targeting IL-12/23 or IL-17 pathways may be considered. | 1b | B | 9.1 ± 1.1 |
| 7. | In patients with peripheral arthritis and an inadequate response to at least one csDMARD in whom bDMARDs are not appropriate, a targeted synthetic DMARD, such as a PDE4 inhibitor, may be considered. | 1b | B | 8.5 ± 1.4 |
| 8. | In patients with active enthesitis and/or dactylitis and insufficient response to NSAIDs or local glucocorticoid injections, therapy with a bDMARD should be considered, which, according to current practice, is a TNF inhibitor. | 1b | B | 9.1 ± 1.2 |
| 9. | In patients with predominantly axial disease that is active and has insufficient response to NSAIDs, therapy with a bDMARD should be considered, which, according to current practice, is a TNF inhibitor. | 1b | B | 9.6 ± 0.6 |
| 10. | In patients who fail to respond adequately to a bDMARD, switching to another bDMARD should be considered, including switching between TNF inhibitors. | 1b | B | 9.6 ± 0.7 |

The level of evidence was determined for different parts of the recommendation (referred to as a and b) where necessary.

The level of agreement was computed as a 0–10 scale.

bDMARD, Biological DMARD; CRP, C-reactive protein; csDMARDs, conventional synthetic DMARDs, such as methotrexate, sulfasalazine or leflunomide; DMARD, disease-modifying anti-rheumatic drugs; ESR, erythrocyte sedimentation rate; EULAR, European League Against Rheumatism; NSAIDs, nonsteroidal anti-inflammatory drugs; PDE, phosphodiesterase; PsA, psoriatic arthritis; TNF, tumour necrosis factor.

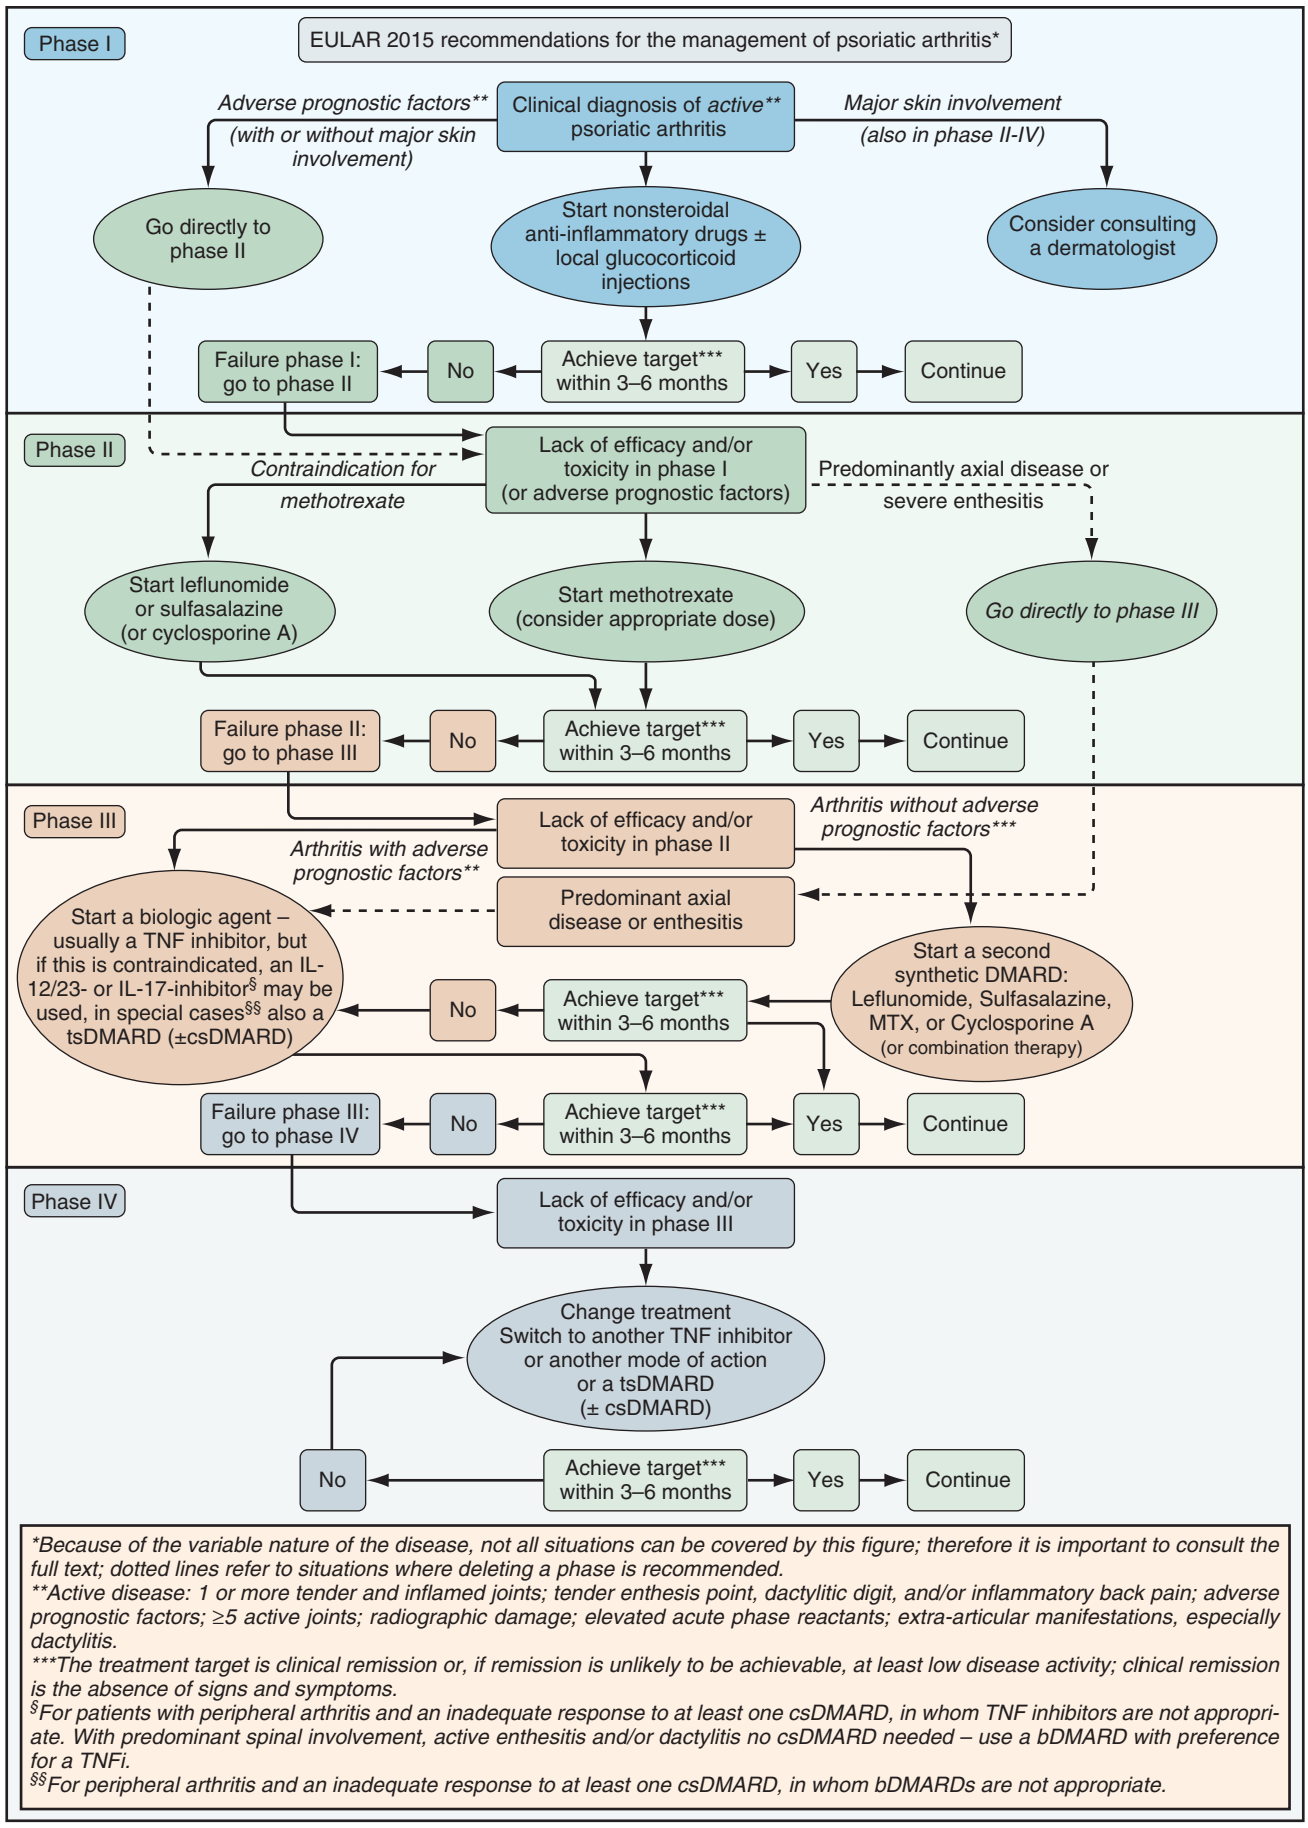

**Figure 77-12** The EULAR 2015 algorithm for treatment of PsA with pharmacological nontopical treatments. bDMARD, Biological DMARD; csDMARDs, conventional synthetic DMARD; DMARD, disease-modifying anti-rheumatic drug; EULAR, European League Against Rheumatism; IL, interleukin; MTX, methotrexate; PsA, psoriatic arthritis; tsDMARD, targeted synthetic DMARD. *(Reproduced from Gossec L, Smolen JS, Ramiro S, et al: European League Against Rheumatism [EULAR] recommendations for the management of psoriatic arthritis with pharmacological therapies: 2015 update.* Ann Rheum Dis *2015 Dec 7. [Epub ahead of print], with permission from BMJ Publishing Group Ltd.)*

Based on evidence and expert opinion, nearly all DMARDs may have small to moderate beneficial effects on peripheral joints, enthesitis, and dactylitis.[124,127,128] Axial features and nail disease do not seem to respond.[129] Good or moderate improvements in skin disease have been reported with some of the older systemic agents, such as methotrexate, cyclosporine, sulfasalazine, leflunomide, and acitretin (all level 1b, grade A).[126]

The best evidence for disease-modifying anti-rheumatic drug (DMARD) use comes from studies of peripheral joint disease and of psoriasis. Six randomized controlled trials have studied the use of sulfasalazine in psoriatic arthritis (level 1a, grade A). The largest study included 221 patients. Of the patients using the PsARC scoring system, 59% achieved a therapeutic response, but consistent with other studies, a high therapeutic response (42.7%) was also noted in placebo-treated patients.[58]

Methotrexate remains for many rheumatologists the DMARD of first choice for patients with psoriatic arthritis, but evidence for its use is limited (level 3, grade B). A small, prospective randomized controlled trial concluded that methotrexate was as effective as cyclosporine. Another study of 72 patients with active psoriatic arthritis and an incomplete response to methotrexate, in which cyclosporine was added, showed significant differences only in synovitis as detected by MSUS and PASI scores in favor of the combination therapy.[33,130] Although evidence for methotrexate is lacking, an open study reported significant reductions in synovial cellular infiltration and in cytokine gene expression after 3 months of therapy.[100] Another randomized placebo-controlled trial of methotrexate in psoriatic arthritis that included 221 patients found no evidence that methotrexate improved synovitis in patients with active psoriatic arthritis,[131] It is worth noting that this trial had a number of limitations. First, it included patients with mild disease (≥1 acute peripheral joint). Second, it allowed for a maximum dose of only 15 mg/week and, finally, it used PsARC as the primary outcome measure, when it has been shown to be associated with high placebo response.

Although evidence suggests that cyclosporine may be as effective as methotrexate, its use is limited because its toxicity profile is considered to be high (level 1b, grade B).[132]

Perhaps the best randomized controlled trial in psoriatic arthritis of a DMARD examined the use of leflunomide (level 1b, grade A).[133] This trial included 190 patients who received leflunomide or placebo for 24 weeks. Of patients treated with leflunomide, 59% of patients met the primary response criteria (PsARC),compared with 30% of patients given placebo, with significant, although small, improvements in other individual parameters, including joint scores, health assessment questionnaire results, PASI, and Dermatology Life Quality Index scores. Regarding some older DMARDs, such as gold salts and anti-malarials, no evidence of treatment benefit has been found; exacerbation of psoriasis has been reported, and these agents cannot be recommended. One small, randomized controlled trial with azathioprine suggested benefit with a reduction in Ritchie score (level 2b, grade B). Finally, apart from the cyclosporine/methotrexate study referred to earlier, little or no evidence suggests that DMARD combination therapy is beneficial or safe in psoriatic arthritis.

With the exception of psoriasis, there is a paucity of evidence that DMARDs are beneficial for the other features of psoriatic arthritis, including dactylitis, axial disease, or enthesitis. Absence of evidence does not mean absence of an effect, however. Further randomized controlled trials that specifically examine these features in psoriatic arthritis are required. In psoriasis, methotrexate and cyclosporine have been shown to be highly and probably equally effective (level 1b, grade A).[126] Adverse effects, in particular with cyclosporine, may limit usage in some patients.

## BIOLOGICS

The approach to treatment in psoriatic arthritis has changed considerably with the introduction of biologic therapies. As a result of numerous large, well-conducted, randomized controlled trials, accumulating evidence indicates that anti-TNF treatments are effective in controlling peripheral arthritis symptoms and signs, improving quality of life, and preventing radiologic progression (overall level 1b, grade A).[124] Indeed, higher rates of DAS28 remission are found in patients with psoriatic arthritis compared with patients with RA after 1 year of anti-TNF therapy.[134] Patients receiving 25 mg subcutaneously twice weekly of etanercept showed significant improvement in ACR20 responses (59% vs. 15%) at 12 weeks compared with placebo.[135] At 12 months, radiographic disease progression (modified total Sharp score) was inhibited in the etanercept group (–0.03 U) compared with worsening of +1.00 U in the placebo group.

Although the anti-TNF therapies have not been compared in any study, their effect on peripheral arthritis seems to be similar. Evidence indicates that anti-TNF therapies are also effective for other disease features, such as nail disease, enthesitis, and dactylitis.[127,128,136] These studies are limited by the absence of a validated instrument to measure these features. With psoriasis, the effects of anti-TNF therapies can be quite dramatic.[137] In particular with antibody therapy, highly significant improvements in PASI scores were achieved (e.g., PASI = 75 in 59% of adalimumab-treated patients vs. 1% in placebo-treated patients after 24 weeks; PASI = 90 in 50%).[138] Better skin but not articular responses have been demonstrated in etanercept patients treated with 50 mg twice weekly as compared with once weekly.[139]

Other TNF inhibitors that have been licensed for the treatment of psoriatic arthritis include golimumab and certolizumab pegol. In a study of 409 patients, ACR20 response was significantly greater in certolizumab pegol, 200 mg every 2 weeks, and 400 mg every 4 weeks-treated patients than placebo (58.0% and 51.9% vs. 24.3% [$P$ <0.001]) at week 12.[140] Golimumab was evaluated in 405 patients. Forty-eight percent of patients receiving golimumab achieved an ACR20 response, compared with 9% of patients in placebo group.[141] Five year data on golimumab confirms clinical efficacy, safety, and inhibition of radiographic progression (mean change in total SHS ≤0.3).

Other novel therapies that target different pathways in psoriatic arthritis have been developed in recent years. Ustekinumab is a fully human IgG1κ monoclonal antibody that binds to the common p40 subunit shared by IL-12 and 23. It has now been approved for psoriasis and psoriatic

arthritis. It has shown significant and sustained improvements in psoriatic arthritis signs/symptoms in a diverse population of patients with active psoriatic arthritis (ACR20, 43.8% ustekinumab-treated group vs. 20.2% placebo). At 12 months, ustekinumab was shown to inhibit radiographic progression of joint damage (Change in PsA-modified van der Heijde-Sharp (vdH-S) score from baseline to week 52; 1.2 ± 5.4, 0.6 ± 2.6, 0.7 ± 3.7 for placebo, ustekinumab, 45 mg and 90 mg, respectively).[142] There is accumulating evidence that IL-17 is central to the pathogenesis of psoriatic arthritis. The blockade of IL-17A has been proposed as a therapeutic target in the treatment of psoriatic arthritis. Secukinumab is a fully human, high-affinity, anti-IL-17A monoclonal antibody that binds to and neutralizes IL-17A. Secukinumab has been recently approved for both psoriatic arthritis and ankylosing spondylitis. In a phase 3, double-blind, placebo-controlled trial, 397 patients with psoriatic arthritis were randomly assigned to receive subcutaneous secukinumab 300 mg ($n$ = 100), 150 mg ($n$ = 100), 75 mg ($n$ = 99), or placebo ($n$ = 98) once a week from baseline and then every 4 weeks from week 4. A significantly higher proportion of patients achieved an ACR20 at week 24 with secukinumab 300 mg (54%, $P$ <0.0001), 150 mg (51%, $P$ <0.0001), and 75 mg (29%, $P$ = 0.039) versus placebo (15%). Moreover, 52-week data from the same study suggests that efficacy of secukinumab is sustained over long periods.[143] Inhibition of IL-17 signaling by brodalumab—a human monoclonal antibody against IL-17 receptor A (IL-17RA)—also induced significant clinical responses in patients with psoriasis. In a recent study in patients with PsA, ACR20 response at week 12 was achieved in 37% and 39% in patients receiving 2 doses of brodalumab versus 18% receiving placebo. These findings show that IL-17RA is a potential target for the treatment of psoriatic arthritis, with the inhibition of downstream pathways associated with improvements in arthritis, psoriasis and physical function.[144] There is early promise of JAK inhibitors in both psoriasis and psoriatic arthritis. A possible mechanism might be down regulation of the IL-23 receptor, which in turn might affect IL-17 expression.[144a] Finally, apremilast—a non-biologic small molecule that inhibits phosphodiesterase 4—has now been approved in the United States by the U.S. Food and Drug Administration for the treatment of psoriatic arthritis. At week 16, more apremilast, 20 mg BID (31%), and 30 mg BID (40%) patients achieved ACR20 versus placebo (19%) ($P$ <0.001). Apremilast demonstrated an acceptable safety profile and was generally well tolerated.[145]

Recently, the role of methotrexate as a co-medication in anti-TNF inhibitor treatment for psoriatic arthritis has been evaluated by using the Norwegian DMARDs registry. The study analyzed 440 patients, 170 on anti-TNF only and 270 on combination therapy methotrexate-anti-TNF. Results showed that anti-TNF drug survival of the group on co-medication with methotrexate was superior to those not on methotrexate. The effect was mainly seen in those on infliximab, which leaves open the possibility of a role for methotrexate in inhibiting development of drug antibodies when patients are treated by monoclonal antibodies.[146] The first study that used a treat-to-target approach in psoriatic arthritis has very recently been published. In the study, 206 patients were randomly assigned to either tight control (step-up regimen aiming for minimal disease activity by using methotrexate, combination DMARDs, and anti-TNF) or to standard care. In the tight control group, 61.7% achieved ACR20 response compared with 44.6% in the standard care group. There were more adverse events in the tight control but no unexpected serious adverse event.[147] This study highlights the possibility of adopting a treat-to-target approach in psoriatic arthritis and accepting minimal disease activity as a potential target in the future.

Alefacept, a fusion protein of soluble lymphocyte function antigen 3 with Fc fragments of IgG1, that was approved for the treatment of psoriatic arthritis, has since been withdrawn because of a business decision by its manufacturer. Efalizumab, a monoclonal antibody that was approved for the treatment of psoriasis, has also been withdrawn because of safety issues.

In summary, the therapeutic options for psoriatic arthritis continue to expand, and modern biologic therapies mean that psoriatic arthritis patients are reaching levels of disease control previously not thought possible.

However, these drugs are expensive and place a huge burden on health systems. It is noteworthy that some patients do not respond to biologics, and some treatments may lose efficacy with time, or patients may begin to experience intolerable side effects.

CHAPTER 78

# Enteropathic Arthritis

Frank A. Wollheim

**KEY POINTS**

- The gut wall is a leaky barrier exposed to commensal and pathogenic microorganisms.
- Microbiota are essential for maturation and regulation of the immune system.
- Gastrointestinal lymphoid tissue–microbiota interaction balances between inflammatory defense and tolerance.
- Genetic polymorphisms in Crohn's disease can result in relative immune deficiency.
- Some types of joint disease in inflammatory bowel disease are genetically determined.
- Human leukocyte antigen-B27 locus interacts with non-major histocompatibility complex genes as a determinant of disease risk.
- Celiac disease is surprisingly common in adults, 25% of whom have joint manifestations.
- Patients with Whipple's disease often present with joint symptoms.
- Microscopic colitis is accompanied by extraenteric autoimmune manifestations.

Interest in gut microbiota and their role in the pathogenesis of human disease has increased in recent years, resulting in more than 2000 publications on the topic in 2013 alone. A number of diseases, including obesity, irritable bowel syndrome, and rheumatoid arthritis (RA), appear to be linked to changes in the gut microbiota. This chapter will begin with an update on gut physiology, intestinal microbiota, and the gut-associated lymphoid system (GALT). It will then address musculoskeletal problems associated with inflammatory bowel disease (IBD), celiac disease (CeD), and other less common conditions with prominent gut involvement. Reactive arthritis, although often triggered by pathogenic microorganisms in the gastrointestinal (GI) tract, is addressed in Chapter 76. Knowledge regarding the signals from the gut which generate joint disease still remains incomplete. The fine tuning of permeability, the interactions between the microbiota and cells in the gut mucosa, and the biology of GALT and its role in the development of arthritis are the main topics addressed in this chapter.

## GUT MUCOSA BIOLOGY

**KEY POINTS**

- The gut is covered by mucin, which forms an unstirred layer.
- The gut epithelium is impermeable to most hydrophilic solutes.
- The epithelial tight junctions regulate gut wall permeability.
- Myosin light-chain kinase is a regulator of tight junction and is influenced by TNF.
- Disturbed gut wall permeability is present in several diseases, including non-alcoholic fatty liver disease.

The GI tract has three major functions. It serves as a barrier against hostile environmental factors, it performs fluid and food absorption and excretion of waste products, and it produces major trophic host functions. The surface area of the gut mucosa was previously considered as large as a tennis court. However, new research indicates a surface measurement of "only" 32 $m^2$.[1] The mucosa is constantly exposed to potentially harmful environmental agents against which defense is essential, but tolerance toward normal microflora, referred to as *microbiota*, must also be maintained. To fulfill its diverse functions, the gut can be considered an immunologically privileged organ.[2]

The gut epithelium functions as a so-called *leaky* barrier. It consists of intestinal epithelial cells, including Paneth cells in deep crypts, mucus-secreting goblet cells, M cells, and cells of the innate and adaptive immune system. It is covered by a thin layer of fluid separated from luminal flow and peristalsis of the intestine by mucin, the "unstirred layer," which slows down the diffusion of solutes and reduces loss of digestive enzymes. An increased thickness of the unstirred layer may contribute to malabsorption in CeD. Underneath the basal membrane is the lamina propria, which contains immune cells, including lymphocytes, dendritic cells (DCs), and macrophages.[2] The plasma membrane of the epithelial cells is impermeable to most hydrophilic solutes in the absence of specific transporters. The structure of the interepithelial paracellular space consists of the tight junction, the adherens junction, and the desmosome (Figure 78-1B). The tight junction is considered

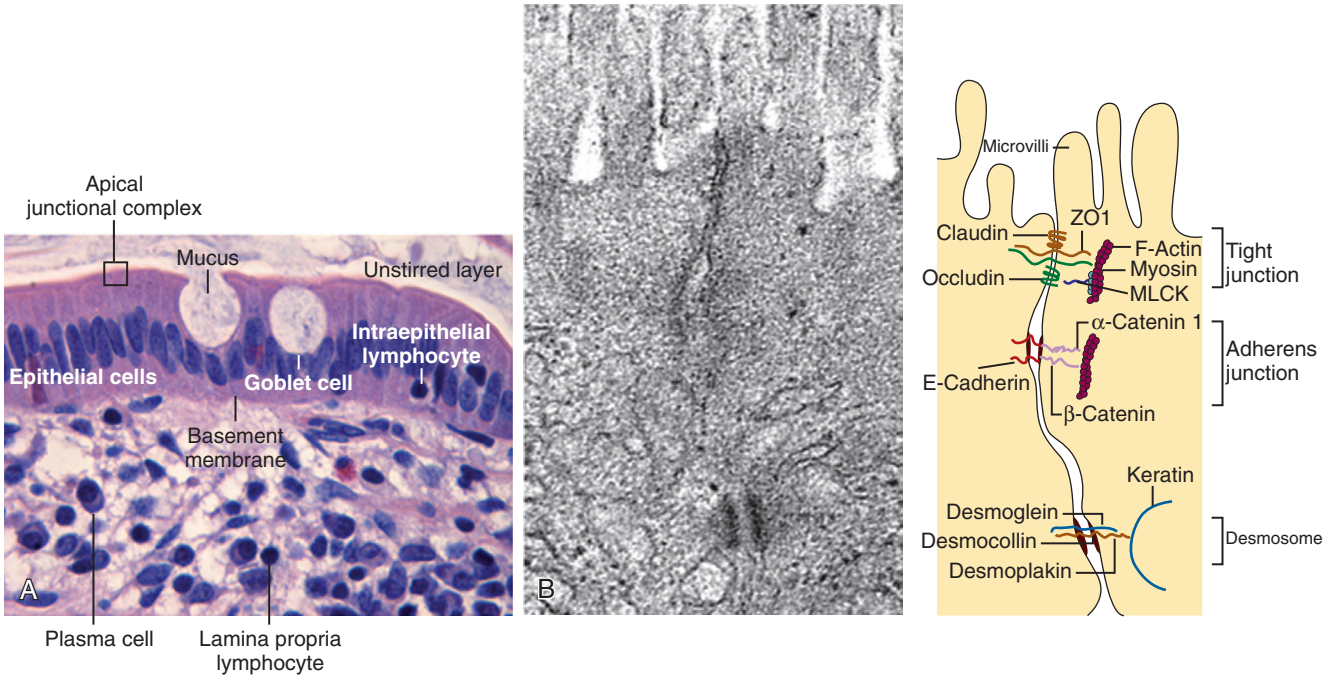

**Figure 78-1** Anatomy of the mucosal barrier. **A,** The human intestinal mucosa is composed of a simple layer of columnar epithelial cells, as well as the underlying lamina propria and muscular mucosa. Goblet cells, which synthesize and release mucin, as well as other differentiated epithelial cell types, are present. The unstirred layer, which cannot be seen histologically, is located immediately above the epithelial cells. The tight junction, a component of the apical junctional complex, seals the paracellular space between epithelial cells. Intraepithelial lymphocytes are located above the basement membrane but are subjacent to the tight junction. The lamina propria is located beneath the basement membrane and contains immune cells, including macrophages, dendritic cells, plasma cells, lamina propria lymphocytes, and, in some cases, neutrophils. **B,** An electron micrograph and corresponding line drawing of the junctional complex of an intestinal epithelial cell. Just below the base of the microvilli, the plasma membranes of adjacent cells seem to fuse at the tight junction, where claudins, zonula occludens 1 (ZO1), occludin, and F-actin interact. E-cadherin, α-catenin 1, β-catenin, catenin δ1 (also known as *p120 catenin;* not shown), and F-actin interact to form the adherens junction. Myosin light-chain kinase (MLCK) is associated with the perijunctional actomyosin ring. Desmosomes, which are located beneath the apical junctional complex, are formed by interactions among desmoglein, desmocollin, desmoplakin, and keratin filaments. *(From Turner JR: Intestinal mucosal barrier function in health and disease.* Nat Rev Immunol *9:799–809, 2009.)*

rate limiting for permeability. A perijunctional actomyosin ring condensation is regulated by myosin light-chain kinase (MLCK), which has a central role in regulating tight junction transport and in TNF-induced permeability increase.[3] TNF inhibition will influence permeability via inhibition of MLCK transcription. Overexpression of MLCK, on the other hand, results in increased permeability and activation of immune cells in transgenic mice.[4] Although initially healthy, these mice were prone to accelerated colitis if challenged.

Solutes smaller than 5000 Da can pass through the epithelium freely, whereas bacterial products and dietary antigens are dependent on active transport mechanisms. Altered gut permeability can be observed in several diseases, including nonalcoholic fatty liver disease.[5] In this condition, alterations in the expression of zona occludens 1 (ZO1) result in perturbation of permeability. Genetic and exogenous factors, such as drugs, nicotine, microorganisms,[6] and cytokines, are potential triggers of pathology by influencing paracellular functions in the gut epithelium.

Mucosal permeability and transport can be assessed by oral feeding of lactalbumin, lactoglobulin, polyethylene glycol particles, $^{51}$Cr-labeled ethylenediaminetetraacetic acid (EDTA), and sugars such as lactulose and mannitol, followed by urinalysis. In addition, intestinal permeability and function can be studied by regional perfusion with the help of endoscopic techniques that close off segments of the gut with inflatable balloons.[7] A study that applied enzyme-linked immunosorbent assays to fluid collected by this technique showed marked local immunity to a number of food-related antigens in patients with RA.[8] Ethnic differences in gut permeability have also been described.[9]

## GUT MICROBIOTA

**KEY POINTS**

**The gut microbiota contain 10 times more bacteria than the cells in the human body. Segmented filamentous bacteria cause dysbiosis by stimulating IL-17 formation.**

**Bacteria stimulate Toll-like receptor 5 signals in the mucosa, which enhances systemic immune response.**

**Environmental influences on risk for arthritis include antibiotics, smoking, and stress.**

The human gut lumen harbors 90% of all cells of our biome and contains trillions of microorganisms and more than 1000 different species.[2] This gut microbiota consists of a mixture of native bacteria acquired at birth or shortly thereafter that retains a relatively constant composition. It also has a smaller population of transient bacteria of varying

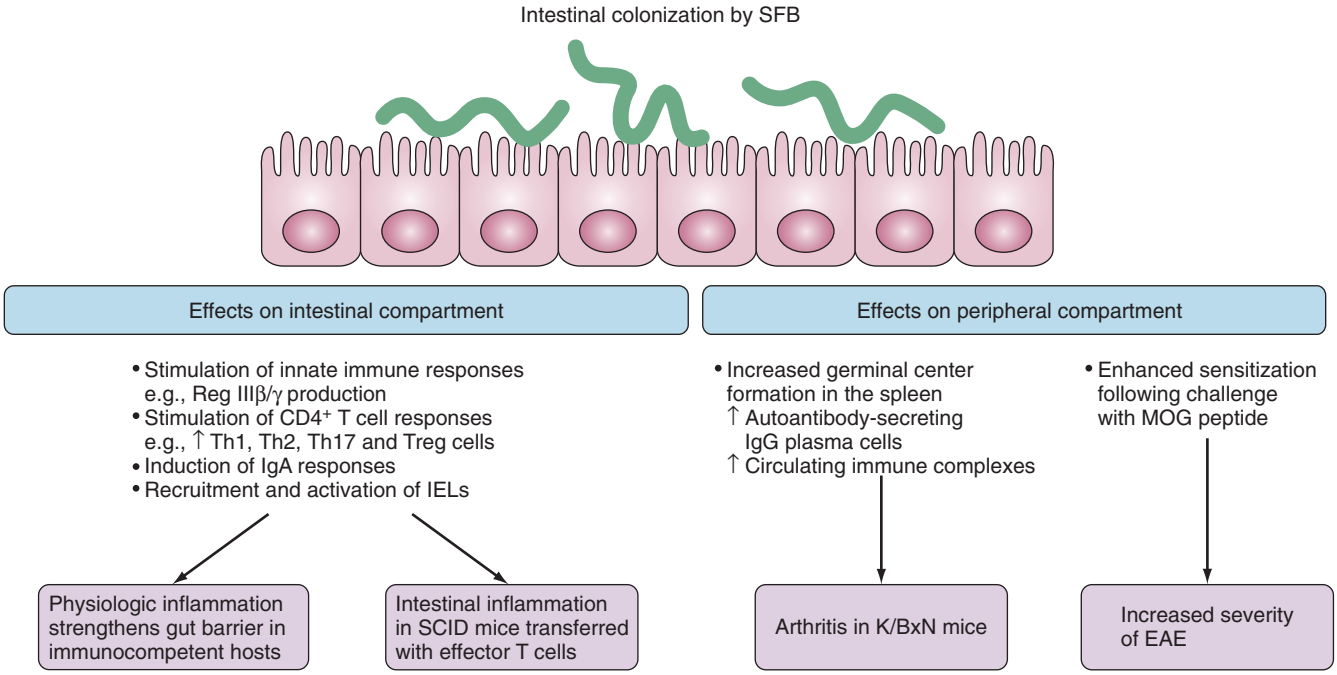

**Figure 78-2** Effects of colonization of the gut immune system. Segmented filamentous bacteria (SFB) are spore-forming bacteria that are related to the genus *Clostridium*.[51] Inherited from the mother microbiota, SFB develop strong interactions with the ileal mucosa, and in immunocompetent mice, the bacteria can largely recapitulate the inducing effects of the whole microbiota on the postnatal maturation of the gut immune system. SFB induce the production of Reg IIIβ/γ microbicidal peptides,[23,45] which protect against colonizing pathogens.[46] Additionally, SFB simultaneously activate strong secretory immunoglobulin (Ig)A responses,[44] induce the recruitment and activation of cytotoxic intraepithelial lymphocytes (IELs), and drive various T cell responses, including a robust T helper (Th) 17 cell response.[28,45] In immunocompetent mice, SFB-induced pro-inflammatory and regulatory responses balance each other, which results in physiologic inflammation that strengthens the gut barrier. By contrast, colonization by SFB promotes the development of colitis in severe combined immunodeficient (SCID) mice that have been reconstituted with effector T cells.[52] Intestinal colonization by SFB can also promote the development of inflammatory diseases outside of the gut. SFB promote arthritis in autoimmune nonobese diabetic (NOD) mice that express a transgenic T cell receptor (TCR) that is specific for a self-peptide (known as K/BxN mice), an effect ascribed to the induction of Th17 cells.[54] SFB also enhance the severity of myelin oligodendrocyte glycoprotein (MOG)-induced experimental autoimmune encephalomyelitis (EAE). These aggravating effects may reflect the strong adjuvant properties of SFB. Treg, T regulatory. *(From Cerf-Bensussan N, Gaboriau-Routhiau V: The immune system and the gut microbiota: friends or foes?* Nat Rev Immunol *10:735–744, 2010.)*

composition. The former are essential for health and live in symbiosis; the latter contain potential pathogens. Prolonged administration of antibiotics to neonates impedes colonization and increases the risk of late-onset sepsis, demonstrating the protective role of the microbiota.[26] Whereas the stomach and duodenum normally contain less than $10^3$ mucosa-adhering bacteria, the number of bacteria increases to $10^4$ in the jejunum and $10^7$ in the ileum. Most of the latter group comprises gram-negative aerobic species. In the colon, the bacterial density is $10^{12}$ or more, consisting mostly of anaerobic bacteria. Transit time is fast in the upper gut and slow in the distal gut, but the immunologic impact of the microbiota is higher in the proximal parts of the gut.[10] One can also distinguish between luminal and mucosal microbiota.

In addition to culturing, the microbiota can be studied by molecular methods, the most sensitive of which is analysis of the 16S bacterial ribosomal RNA gene sequence. This analysis has revealed the presence of a bewildering number of phylotypes. Consequently, the number of genes in the microbiota is estimated to be 150 times greater than that of the human genome.[11] Interactions with host cells has a profound influence on adaptive immunity. The molecular and cellular mechanisms have mainly been studied in animal models. The phenotype of the K/BxN mouse model of autoimmune arthritis was found to be strongly attenuated under germ-free conditions and in mice fed a pathogen-free mix of bacteria. The introduction of a single species of segmental filamentous bacteria to these animals, however, triggers arthritis by activating autoreactive Th17 effector cells in lamina propria (Figure 78-2).[45] Researchers have found that the effect is mediated by interfering with intrinsic T cell desensitization in the mucosa.[12] Vaccination of germ-free animals results in subnormal responses. Introduction of certain bacteria can normalize the response in mice; this process is mediated by enhanced release of Toll-like receptor 5 (TLR5) from the gut.[13] A similar mechanism could be involved in the mediation of enteropathic arthritis.

Bacteria digest food carbohydrates into short-chain fatty acids, which facilitate the absorption of $Ca^{2+}$, $Mg^{2+}$, and $Fe^{2+}$ ions. They also synthesize amino acids and vitamins, and secrete antibacterial protective substances. Genetic and environmental factors, including stress, may alter the gut microbiota and shift a state of homeostasis into one of imbalance or *dysbiosis*, as will be discussed later. Understanding host-microbiota interactions still is hampered by methodological challenges. Extrapolation of mouse data should be made with some caution.[14] However, exploration of the microbiota is expected to give better insight into the pathophysiology of several conditions, including enteropathic arthritis, and help to generate therapeutics.

## Gastrointestinal-Associated Lymphoid Tissue

**KEY POINTS**

- Microbiota influences regulate gastrointestinal-associated lymphoid tissue.
- Innate and adaptive immune cells constitute 80% of the intestine.
- Retinoic acid promotes immunoglobulin (Ig)A and lymphocyte homing.
- Flagellin stimulates DCs to induce T helper 17 cells.
- Vascular adhesion protein 1 is expressed in the gut and synovium and is a putative therapeutic target.
- Gut homing lymphocytes express integrins like α4β7 and αEβ7 as well as the chemokine receptor CCR9.

GALT is the largest lymphoid organ of the body, constituting 25% of the mucosal mass. Cellular components of GALT are localized in Peyer's plaques, gut lymphoid follicles, lamina propria, and intraepithelial T cells. GALT is part of a complex defense and tolerance-regulating system that involves specialized DCs and intestinal epithelial cells IECs (Figure 78-3). Commensal bacteria interact with IECs, which send signals to DCs mediated by anti-inflammatory substances (e.g., thymic stromal lymphopoietin [TSLP]) and to lamina propria DCs. Bacteria also interact directly with DCs by means of their polysaccharide A. A subset of lamina propria DCs expresses $CD11b^{hi}$, $CD11c^{hi}$, and TLR5. When exposed to bacterial flagellin, these DCs promote the differentiation of T helper (Th)17 cells. These DCs also produce retinoic acid. IEPs also produce retinoic acid from dietary vitamin A, APRIL (a proliferation-inducing ligand), and B cell–activating factor (BAFF). Retinoic acid stimulates the expression of the integrin α4β7 and CCR9, thereby influencing gut-homing lymphocytes.[15] Wnt–β-catenin signaling is required for the stimulation of expression of anti-inflammatory mediators by intestinal DCs.[16] Bacteria can also directly penetrate Peyer's patches (PPs) and create a symbiotic environment with host cells.[17] Cytokines such as IL-10 and transforming growth factor (TGF)-β serve anti-inflammatory functions. Retinoic acid, APRIL, and BAFF contribute to the dominating IgA production in local lymphoid cells. Gut enterochromaffin cells produce 5-hydroxytryptamine, which has anti-inflammatory effects and chromogranins with both pro-inflammatory and anti-inflammatory effects.[18]

Some of these not fully understood interactions are depicted in Figure 78-4. Plasma cells in the lamina propria become programmed to produce IgA, but the production is also skewed to formation of dimeric IgA, polymeric immunoglobulin A (pIgA), in which the monomers are connected by joint, or J, chains.[19] Intestinal epithelial

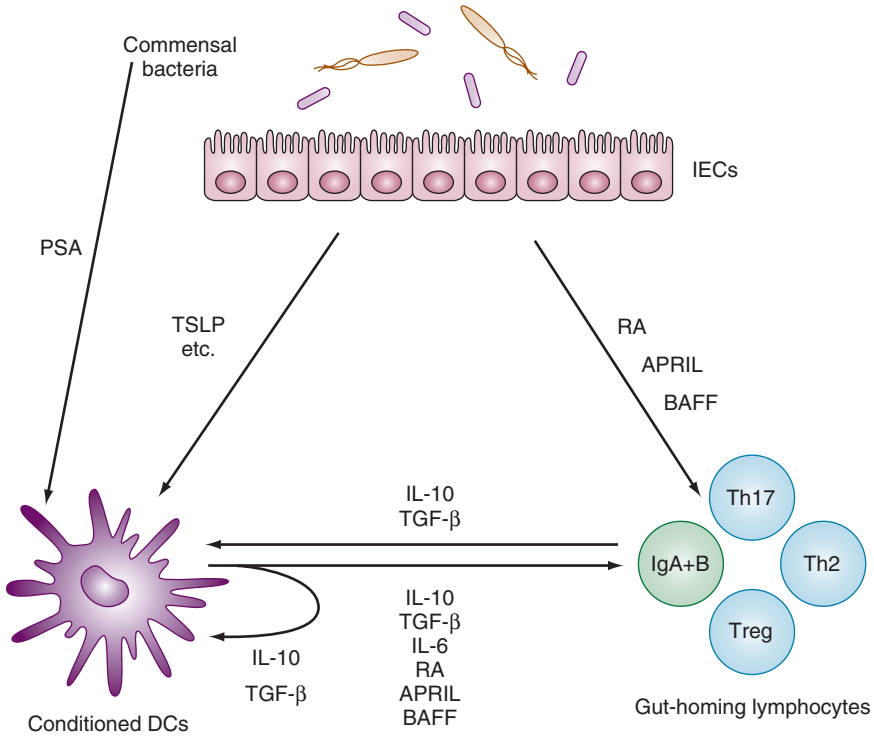

**Figure 78-3** Tolerance induction machinery in the gut. Under the influence of commensal bacteria and their products, conditioned intestinal epithelial cells (IECs) constitutively produce anti-inflammatory molecules, such as thymic stromal lymphopoietin (TSLP), to limit inflammation-induced signals, leading to the development of tolerogenic dendritic cells (DCs). Tolerogenic DCs might also be induced by direct stimulation with *Bacteroides fragilis*–derived polysaccharide A (PSA). Once the tolerogenic DCs are developed, they preferentially produce critical factors for the induction of Th2 cells, T regulatory (Treg), Th17 cells, and immunoglobulin $(Ig)A^+$ B cells. IECs also produce retinoic acid (RA), a proliferation-inducing ligand (APRIL), and B cell–activating factor (BAFF) belonging to the tumor necrosis factor family, which probably affect the development of these lymphocyte subsets. Communication among the commensal flora, IECs, and gut immune system is bidirectional, but only a part of the bidirectional communication is shown in this figure. IL, Interleukin; TGF-β, transforming growth factor-β. *(From Tezuka H, Ohteki T: Regulation of intestinal homeostasis by dendritic cells.* Immunol Rev *234:247–258, 2010.)*

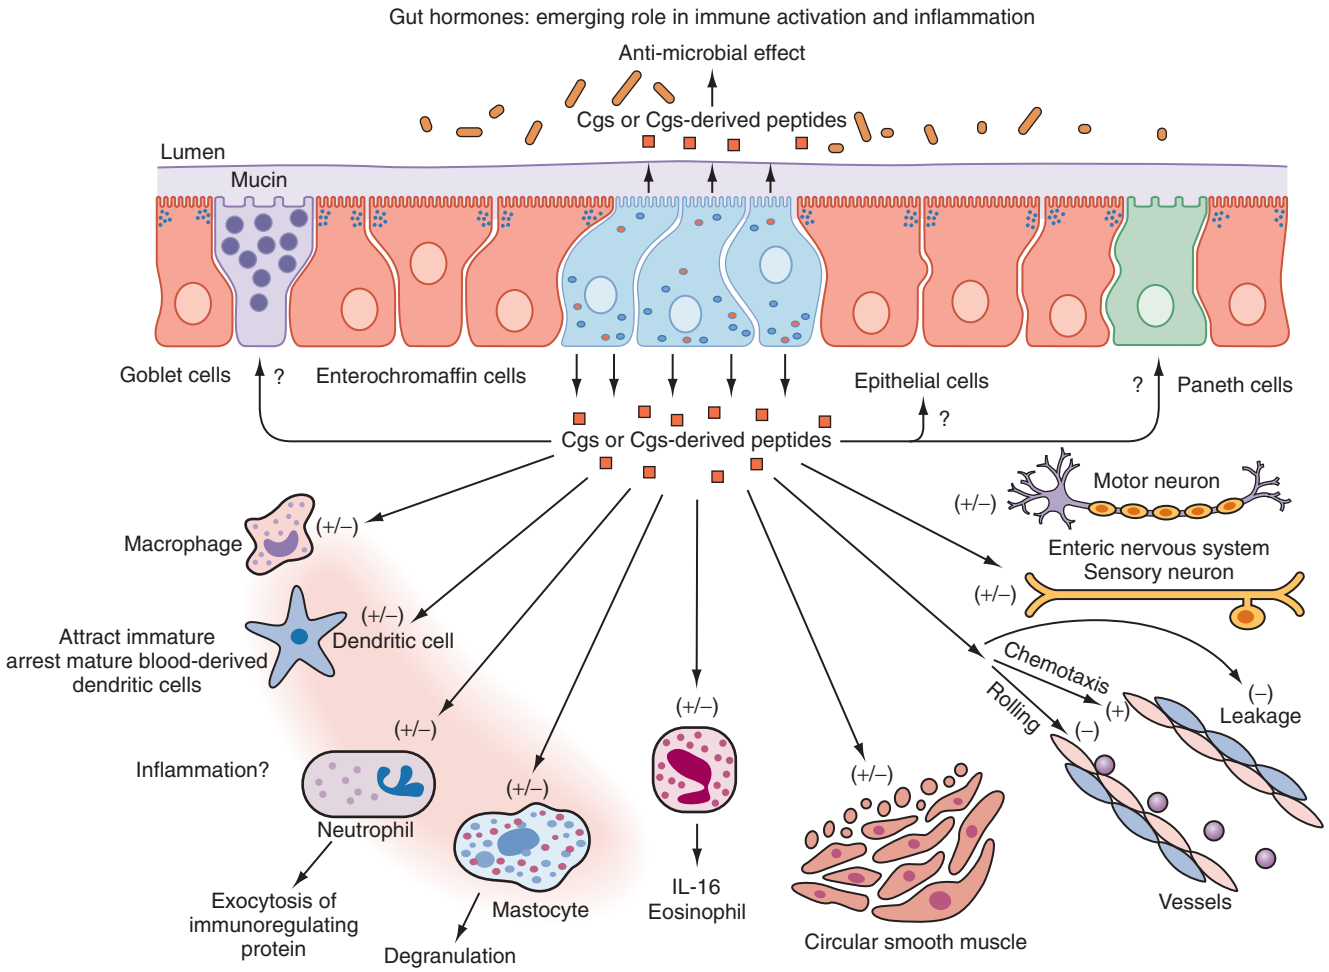

**Figure 78-4** Putative role of chromogranins (Cgs) in immune activation and inflammation. Luminal or internal inflammatory stimuli causes alteration in Cgs or Cgs-derived peptides release. They may act locally on Paneth, goblet, and epithelial cells, as well as on immune cells such as macrophages, dendritic cells, neutrophils, mastocytes, and eosinophils. Endothelial permeability, chemotaxis, rolling, smooth muscle contractility, and the enteric nervous system can also be modulated. IL-16, Interleukin-16; –, inhibition; +, activation. *(From Khan WI, Ghia JE: Gut hormones: emerging role in immune activation and inflammation.* Clin Exp Immunol *161:19–27, 2010.)*

glycoprotein pIgR, a polymeric immunoglobulin receptor that is also called *secretory component* (SC), is produced in IECs. It is a 100 kDa transmembrane receptor for pIgA and IgM. SC/pIgR is abundantly present in PPs in the distal ileum. The pIgR in IECs combines with pIgA and to a lesser extent with IgM to form secretory IgA, secretory IgA (sIgA), and sIgM, respectively, which are exported into the lumen and constitute a non-inflammatory, non–complement-binding first line of defense. It is estimated that a healthy adult secretes 3 to 5 g of sIgA into the gut daily (Figures 78-5 and 78-6).[19] Breastfeeding provides the newborn with abundant sIgA and sIgM, which confers passive protection and also regulates much of the child's immune system[20] (Figure 78-7).

From the PP, primed B lymphocytes disseminate throughout the body's mucous membranes, notably to other parts of the alimentary tract (Figure 78-5). Primed T lymphocytes also disseminate into the circulation and lymph nodes and home into target organs such as salivary glands (in Sjögren's disease), lungs, and synovium.[20] Vascular adhesion protein 1 (VAP-1) expressed on synovial epithelial cells is involved in lymphocyte homing, and P-selectin is a part of macrophage recruitment. VAP-1 is a bifunctional glycoprotein with both adhesive and amino-oxidative properties. Both monoclonal antibodies and small molecular inhibitors are in development for potential use in inflammatory and malignant disease.[21] Monoclonal antibodies are protective against collagen-induced arthritis.[21] Most T lymphocytes in the mucosal lamina propria are $CD4^+$, whereas intraepithelial T cells are mostly $CD8^+$. Gut-associated lymphocytes preferentially express the integrins $\alpha4\beta7$ and $\alpha E\beta7$ and the integrin receptor CCR9 on stimulation by intestinal DCs.

Functional characterization of innate (ILC) and adaptive lymphoid cells distinguish new subsets of ILCs, natural killer (NK) cells, ITi, ILC-22, ILC-17, and type 2 ILC. They activate different sets of effector T cells and are instrumental in the fine tuning of local immune responses. Type 2 ILCs, originally referred to as *nuocytes*, are involved in stimulating IL-13 production and mediating experimental colitis.[22]

Intestinal DCs play a key role in regulation of the intestinal immune response to foreign antigens. DCs are present

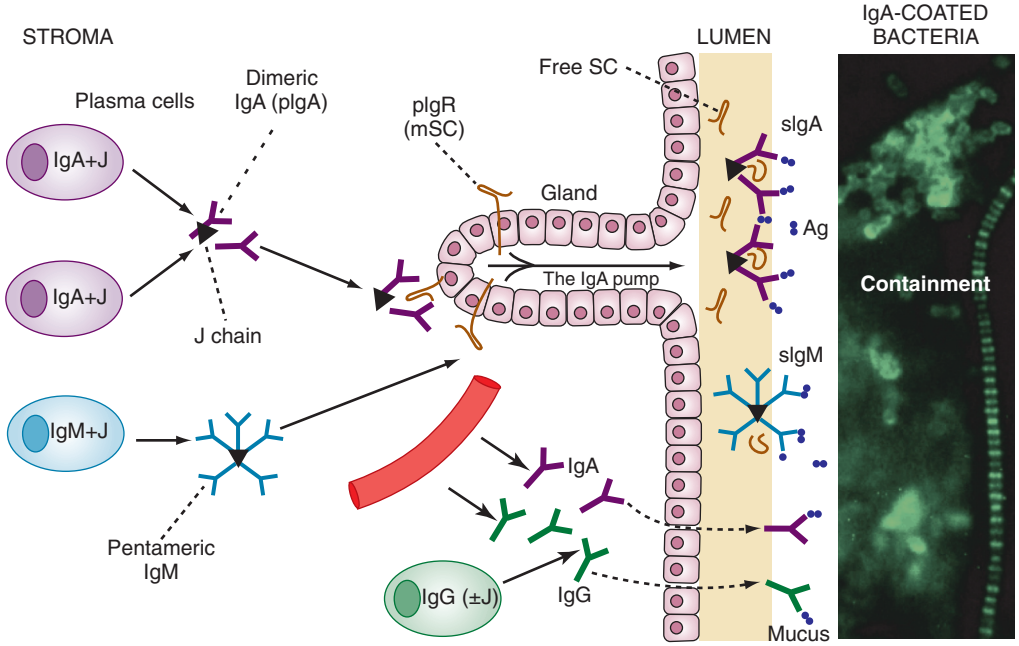

**Figure 78-5** Receptor-mediated export of dimeric immunoglobulin (Ig)A and pentameric IgM to provide secretory antibodies (sIgA and sIgM) that function in immune exclusion of antigen (Ag) at the mucosal surface. Polymeric Ig receptor (pIgR) is expressed basolaterally as membrane secretory component (mSC) on secretory epithelial cells and mediates transcytosis of dimeric IgA and pentameric IgM, which are produced with incorporated J chain (IgA + J and IgM + J) by mucosal plasma cells. Although J chain is often produced by mucosal IgG plasma cells (70% to 90%), it does not combine with this isotype and is therefore degraded intra-cellularly as denoted (± J). Locally produced (and serum-derived) IgG is therefore not subject to pIgR-mediated transport, but can be transmitted paracellularly to the lumen together with monomeric IgA as indicated. Free SC (depicted in mucus) is generated when pIgR in its unoccupied state *(top basolateral symbol)* is cleaved at the apical face of the epithelium-like bound SC in sIgA and sIgM. Commensal bacteria in the right-hand panel are coated in vivo with sIgA, which aids their containment and thereby promotes host-microbial mutualism. *(From Brandtzaeg P: Mucosal immunity: induction, dissemination, and effector functions.* Scand J Immunol *70:505–515, 2009.)*

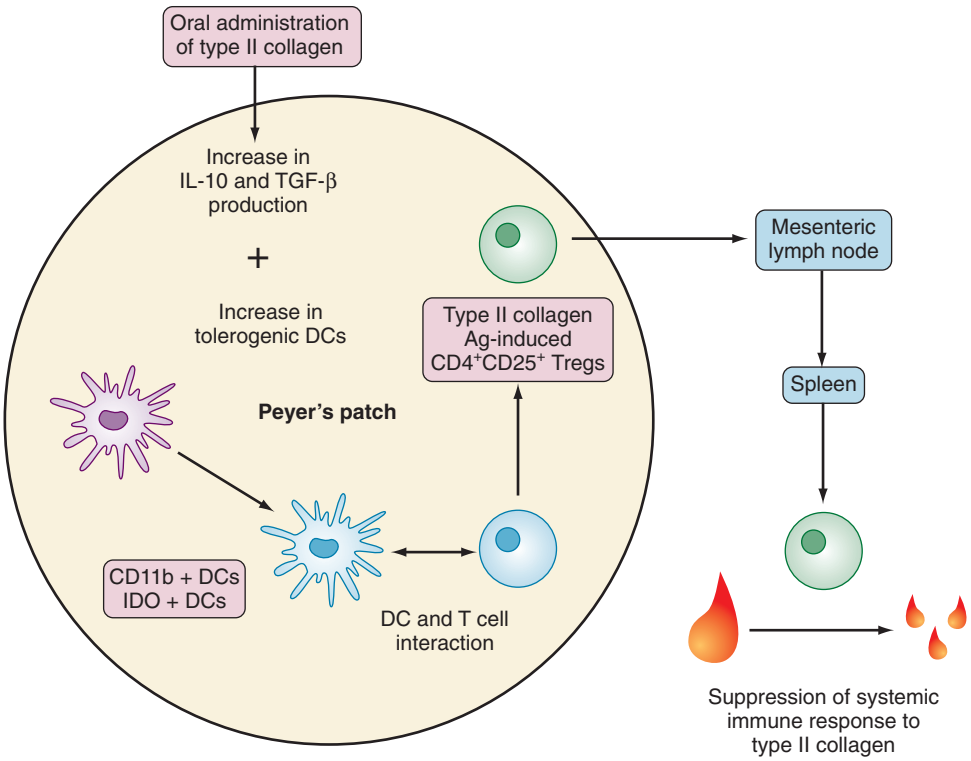

**Figure 78-6** Role of Peyer's patch (PP) dendritic cells (DCs) in type II collagen oral tolerance. As a result of repeated oral administration of type II collagen, the production of anti-inflammatory cytokines such as interleukin (IL)-10 and transforming growth factor-β (TGF-β) by PP cells is enhanced, and the populations of $CD11c^+CD11b^+$ DCs and $IDO^+$ DCs are increased in PP. Then, through DC–T cell interaction, type II collagen inducible $CD4^+CD25^+Foxp3^+$ and regulatory T cells (Tregs) are generated in the PP. Tregs generated in the PP move to the mesenteric lymph node and then enter the systemic circulation, where they suppress the systemic immune response to CII. *(From Park KS, Park MJ, Cho ML, et al: Type II collagen oral tolerance; mechanism and role in collagen-induced arthritis and rheumatoid arthritis.* Mod Rheumatol *19:581–589, 2009.)*

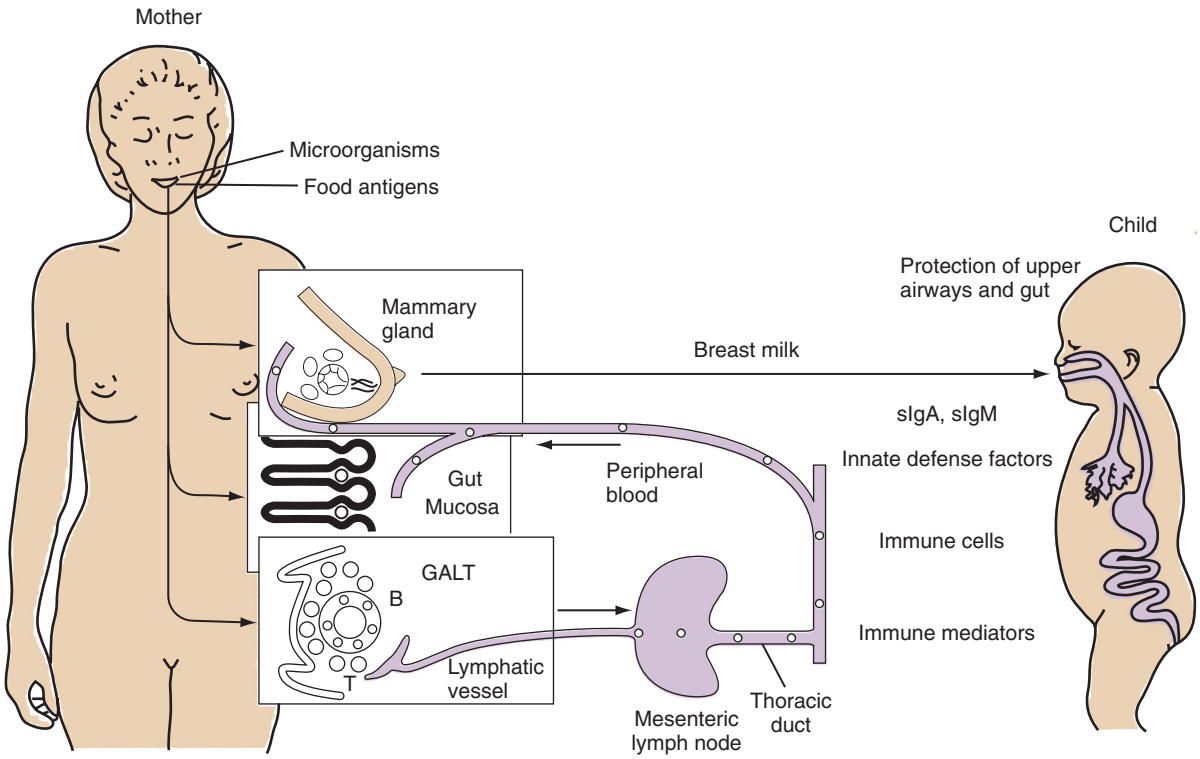

**Figure 78-7** Integration of mucosal immunity between mother and newborn. Primed B (and probably T) cells from Peyer's patch migrate via lymph and peripheral blood to the lactating mammary gland, resulting in the presence in breast milk of secretory immunoglobulin (Ig) antibodies (sIgA and sIgM) specific for enteric antigens. GALT, Gastrointestinal-associated lymphoid tissue. *(From Brandtzaeg P: Mucosal immunity: integration between mother and the breast-fed infant.* Vaccine *21:3382–3388, 2003.)*

throughout the GALT compartment, and migratory DCs can also be identified in mesenteric lymph nodes.[23] Intestinal DCs can be distinguished from macrophages and monocytes by distinct surface markers and their uptake and presentation of the antigenic material monitored. The dynamic control of DC functions by transcription factors and their trafficking to mesenteric lymph nodes indicates that the systemic effects of intestinal DCs may play a key role in the pathogenesis of several gut associated diseases. They may become future targets for therapy.[22] From the circulation thus activated leukocytes can penetrate joint tissue.[24,25]

Induction of oral tolerance to type II collagen has demonstrated how GALT activation may ameliorate inflammatory joint disease (see Figure 78-6). A chain of events in the pathogenesis of enteropathic arthritis can begin with GI infection with the appropriate microorganism in a genetically predisposed patient. This causes local inflammation in the gut mucosa, formation of sIgA, increased permeability, absorption of foreign material, and triggering of T lymphocytes. Circulating immune complexes and memory T cells localize to joints and cause synovitis.

In conclusion, the gut wall is a highly diversified immunologic, endocrine, and digestive organ. Interaction of the gut wall with microbiota results in adjuvant effects, and potentially mediates both protective and harmful signals, resulting in either homeostasis or dysbiosis[26] (see Figure 78-2).

## INFLAMMATORY BOWEL DISEASE

### Epidemiology

**KEY POINTS**

- **The occurrence of IBD has remained constant in Western countries but is increasing elsewhere in the world.**
- **Twin concordance is higher in Crohn's disease than in UC.**
- **Smoking increases the risk in Crohn's disease and ulcerative colitis.**
- **Smokeless nicotine (snuff) may be inert or protective.**
- **Ethnic background influences risk and severity.**

The prevalence and incidence of IBD has historically been markedly higher in North America, Western Europe, Australia, and New Zealand than in other parts of the world. In recent decades, IBD is becoming common in developing countries, South America, Asia, and Eastern Europe, coinciding with the change to more "Western" conditions, such as lifestyle and standard of living. Typically, ulcerative colitis (UC) increases earlier than Crohn's disease (CD). Environmental influences, changes in lifestyle and, consequently, of the microbiota are contributing factors, the study of which could provide clues to the pathogenesis of IBD.[27] The prevalence of CD and UC is approximately equal in many countries and varies between approximately 250 and 150 per 100,000 population for UC, and 300 and 40 for CD

in high-prevalence populations. Prevalence figures below 10 have been reported from most other countries. However, in Japan a notable increase from 5.5 to 63.3 for UC and from 5.9 to 21 for CD, all per 100,000, was noted between 1965 and 2005. Corresponding incidence figures vary between 5 and 20 for UC and 3 and 30 for CD in areas rich in IBD and less than 4 in other places.[28] Ethnic influences also occur. For example, the Jewish population has a higher susceptibility in general, but prevalence approaches that of the background population. In Hungary, Romanies have a remarkably lower risk for IBD compared with the Hungarian population at large.[29]

The incidence of UC and CD in a large Swedish population-based study was 18 and 11 per 100,000 person-years, respectively.[30] Importantly, ever smokers had an elevated relative risk for UC and CD of 1.3 and 1.5, respectively. The overall concordance in monozygotic twins is 36%, but only 16% in UC. This finding indicates a stronger environmental influence in UC.[31] In addition to arthritis, asthma was more prevalent in relatives of Canadian patients with IBD.[32]

## Genetics

**KEY POINTS**

**Genome-wide association studies identified at least 163 single-nucleotide polymorphisms associated with inflammatory bowel disease, 110 of which are common for both Crohn's disease and ulcerative colitis.**

***NOD2* (previously known as *CARD15*), *IRGM,* and *ATG16L1* are associated with DCs.**

***IL23R* and *MDR1* are associated with Crohn's disease and ulcerative colitis.**

***IL23R* deletion protects against colitis in mice.**

The common forms of UC and CD are genetically complex diseases. As of 2012, genome-wide association studies (GWAS) have identified 163 associated single-nucleotide polymorphisms (SNPs), of which 110 are associated with both diseases. Of these SNPs, 23 were associated only with UC, and 30 were associated only with CD, confirming the close relationship but also the distinct nature of the two conditions.[33] The strongest associations, apart from human leukocyte antigen (HLA), are with the *NOD2* (formerly known as *CARD15*) gene on chromosome 16 and the *IL23R* gene on chromosome 1. *NOD2* and *NOD1* are cytosolic sensors for the bacterial peptidoglycan muramyl dipeptide, and trigger the synthesis of antibacterial α-defensins.[34,35] Reduced mucosal expression of these defensins is found in patients with CD.[36] IL-23 signaling can result in activation of Th17 cells in the gut. The importance of IL-23 is supported by the finding that *IL23R*$^{-/-}$ mice are resistant to induction of colitis.[37] Also, IL-23 is upregulated in patients with CD.[38] Another association is found with the transcription factor signal transducer and activator of transcription (STAT)3, which is involved in Th17 activation. STAT3 is present on innate and reactive immune cells and is present in increased amounts in the gut mucosa.[39] Another confirmed genetic association is that with *ERAP1*, an endoplasmic reticulum aminopeptidase previously known as *ARTS1*.[40] *ERAP1* functions by trimming the length of peptides before loading into the grove of HLA, and therefore it could play a role in the triggering of immune reactions in various locations such as gut and joint. A Spanish study of patients with CD looked at the Fc receptor–like 3 *(FcR3)* gene, and found an association with peripheral arthritis.[41] Polymorphisms in this gene are associated with susceptibility to RA and other autoimmune diseases in some populations and, interestingly, *FcR3* may interfere with the Treg function.

*NOD2* mutations were present in 43% of patients in the initial French study,[42] but later population studies found a much lower prevalence in northern European populations, and no correlation in Asians. *NOD2* mutations are not related to susceptibility in the United States. High expression of *NOD2* mRNA has been found in the small intestine, and it is believed to be a regulator of nuclear factor-κB (NF-κB) signaling after the engagement of TLRs. *IBD3* on chromosome 6 has shown the most constant association with IBD, and *HLA-DRB1*0103* has been linked to severe UC in several studies.[24] Further, a TNF microsatellite gene factor was associated with CD but not with UC. HLA-DR2 and DR3 associations have been linked with UC but not with CD.

Mutations of the detoxifying ATP-binding cassette, subfamily B, member 1 gene *(ABCB1)*, also known as *multidrug resistance 1 gene (MDR1)*, are strongly downregulated in unaffected colonic tissue of both CD and UC. *TLR4* and *TLR5* associations have been identified in several populations; this may be of special interest because they act in synergy with *NOD2* and *CARD4* in the induction of proinflammatory cytokines. TLR inhibitors are under investigation for therapeutic efficacy. Recently, researchers found a role for a virus as the contributing trigger in gene-manipulated mice, when mice with a disrupted autophagy gene, *ATG16L1*, were infected with a specific strain of murine norovirus and developed CD-like disease.[38]

A concluding comment regarding genetic association in IBD is that polymorphisms involved in a large number of signaling pathways with relevance for pathogenesis are affected, and that different associations are found in different populations.

## Pathogenesis

IBD is the result of an imbalance between aggressive influences from the lumen and defensive mechanisms in the gut wall. Precise abnormalities of the dysbiosis have been identified in animal models, several but not all of which can be confirmed in patients with IBD. Dysbiosis has been found to be characterized by less diversity of commensals, belonging to *Bacteroides* and Firmicutes phyla, and an increased presence of Proteobacteria.[43,44] Preliminary twin studies indicate different patterns in UC and CD.[45] Dietary factors and treatment with antibiotics could contribute to pathogenic dysbiosis in IBD.

The IECs that form the first line of defense show a diminished formation of defensins in IBD. IECs also have a lower expression of a class I major histocompatibility (MHC)–like transmembrane molecule, CD1d. CD1d cross-linking results in formation of IL-10 and, as a consequence, less IL-10 is formed, which aggravates inflammation.[46]

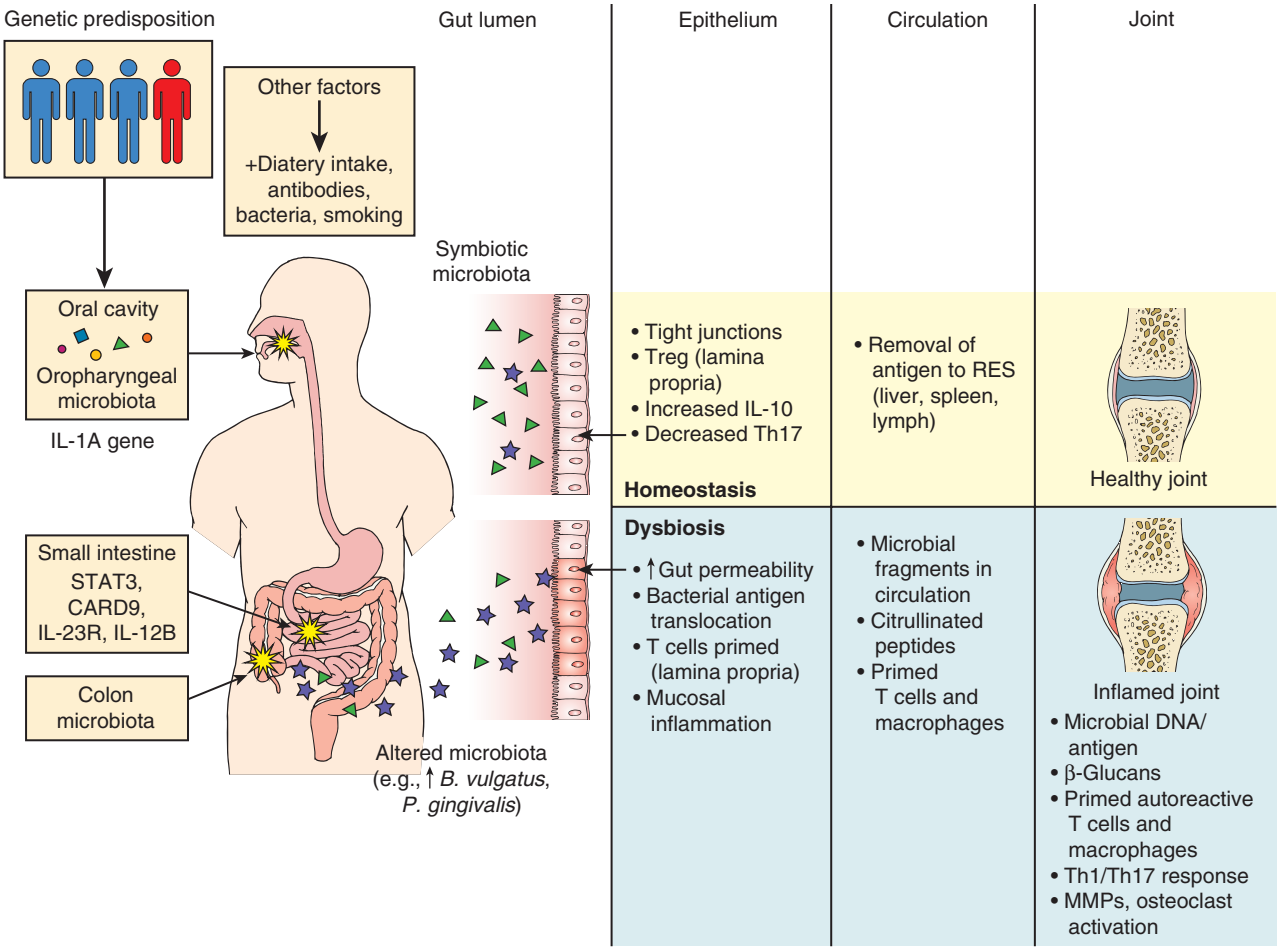

**Figure 78-8** Microbiota-host interaction. Homeostasis versus dysbiosis and putative generation of enteropathic arthritis. **Homeostasis:** Host genetic factors help to preserve the integrity of the epithelial barrier in the oral cavity and intestinal tract. Continual sampling of gut luminal contents enables immune regulation of the inflammatory response (oral tolerance). T regulatory (Treg) cells in the lamina propria assist with an anti-inflammatory environment where such cytokines as TGF-β and IL-10 predominate. Bacteria and antigenic material from the gut which enter the circulation are removed via the reticuloendothelial system (RES) and do not enter the joints. **Dysbiosis:** Host genetic factors contribute to increased intestinal permeability. In the mouth, IL-1A is associated with chronic periodontitis; in the gut, IL-23R, signal transducer and activator of transcription (STAT)3, and CARD9 are associated with intestinal inflammation. Proportions of potentially harmful pro-inflammatory bacteria (e.g., *Bacteroides vulgatus*, *Klebsiella* spp, and sequential batch reactors) are believed to change. Primed T cells and $CD163^{+}$ macrophages from the lamina propria migrate to joints, initiating a pro-inflammatory response mediated by Th1 and Th17 cytokines. Microbial fragments, including β-glucans are lodged in the joints, perpetuating inflammation. In rheumatoid arthritis, citrullinated peptides formed by the action of *Porphyromonas gingivalis* are presented via the shared epitope human leukocyte antigen (HLA)-DRB1, leading to a pro-inflammatory cascade. Within the joint, cytokines upregulate matrix metalloproteinases (MMPs) and osteoclasts, resulting in cartilage destruction and bone erosion. SRBs, Sulfate-reducing bacteria. *(From Yeoh N, Burton JP, Suppiah P, et al: The role of the microbiome in rheumatic diseases.* Curr Rheumatol Rep *15:314, 2013.)*

Several other cytokine disturbances are present in IBD: increased activation of the IL-1 system and decreased ratio of IL-1Ra/IL-1; IL-17A is increased, and IL-17F is present in both UC and CD; IL-33 is increased in UC only. IL-22, on the other hand, promotes IEC healing by STAT signaling, and TNF, IL-6, and IFN-γ are generated by cells both from the innate and adaptive immune system. TNF has a central role in the pathogenesis. Figure 78-8 shows some of these interactions.[47] These cytokine disturbances may contribute to the occurrence of extra-articular manifestations.[48]

Increased gut permeability has already been identified as an important factor in pathogenesis.[7,49] Bacteria recovered from the gut lumen in IBD are covered by immunoglobulin, part of which is circulatory IgG.[50] Increased leakage of tissue fluid from the inflamed mucosa allows the egress of complement-binding IgG, which may contribute to inflammation and further augment permeability. The altered immune response to bacteria differs between CD and UC.[51] Increased gut permeability in IBD is under genetic influence. Basal permeability was healthy in a study of relatives of patients with CD, but it was abnormally increased after the ingestion of acetylsalicylic acid.[52] Environmental influences on permeability may be partly mediated by bacterial endotoxin. An in vitro perfusion study on rat gut showed that serosal rather than mucosal application of endotoxin impairs the barrier.[53] Absorbed bacterial material could therefore add to an already damaged barrier.

The pathogenesis of extraintestinal manifestations (EIM) and complications of IBD involve immune cell migration from the gut. Migratory DCs that carry gut commensals normally are cleared in mesenteric lymph nodes (MLNs), allowing only degraded microbial material to reach the liver via the blood. In a mouse model, MLNs are

overwhelmed and intact microorganisms are cleared first in the liver. The liver may be an important mediator between the gut and EIM in IBD.[49] Not surprisingly, genetics influence the different patterns of EIM. Polymorphisms linked to shared pathogenic pathways can be identified and may, in part, explain the diversity of manifestations.[48]

## Clinical Features

**KEY POINTS**

- **Peripheral arthritis in Crohn's disease and ulcerative colitis occurs as axial disease or peripheral joint disease.**
- **Enthesitis pain is more pronounced than in ankylosing spondylitis.**
- **Uveitis in inflammatory bowel disease is prone to become chronic.**
- **Sclerosing cholangitis develops in 5% of patients with inflammatory bowel disease.**

EIM involve several organ systems in addition to the musculoskeletal and are major contributors to the morbidity and impact of IBD and underline their systemic nature (Table 78-1). Differences exist between UC and CD (Table 78-2). The overall prevalence of EIM may exceed 35%. Spinal involvement occurs in 10% to 20% of cases and may be the only articular manifestation or accompany oligoarthritis.[54] Spinal involvement is often silent, thus its prevalence is underestimated; it may precede the onset of IBD or appear later.[7] In contrast to classic ankylosing spondylitis (AS), there is an equal sex distribution.[55] Radiographic changes are more discrete, squaring of the vertebrae more prevalent, and Romanus lesions unusual. Spinal symptoms do not correlate with intestinal symptoms. Silent CD, on the other hand, is found on biopsy in as many as 30% of patients with early-stage AS.[56] In full-blown IBD-related AS, the prevalence of B27 is only between 50% and 70%.[7] Interestingly, MRI shows more extensive bone marrow edema in IBD-related spondyloarthritis than in AS without IBD.

Peripheral arthritis develops in between 5% and 15% of patients in most studies, slightly more often in patients with CD than in patients with UC (Table 78-3). Peripheral arthritis is more likely to develop in CD patients with large bowel disease (~70%) and intestinal complications, such as fistulas or abscesses, than in patients with disease limited to the ileum.

IBD arthritis is often nondestructive and reversible, but erosive changes may also occur. Limited histopathologic evidence indicates the presence of granulomas in CD and nonspecific synovitis in UC.[7] In CD patients, rapidly destructive septic arthritis has been reported in the hip. Joint symptoms tend to coincide with gut activity in UC but not in CD. Total colectomy is associated with remission of arthritis in half of the patients with UC, but paradoxically, arthritis may also begin after surgery.[57] This may represent a form of bypass arthritis, and is related to altered gut microbiology in a blind loop.

**TABLE 78-1** Extraintestinal Manifestations of Inflammatory Bowel Disease

| | |
|---|---|
| Musculoskeletal | Peripheral arthritis in 5%-20% of patients<br>Type I self-limiting oligoarthritis, activity related<br>Type II progressive polyarthritis, unrelated to activity<br>Proximal arthritis/ankylosing spondylitis in 15%-20%, unrelated to activity |
| Mucocutaneous | Erythema nodosum 10%-15%, related to activity<br>Pyoderma gangrenosum, 1%-5%<br>Sweet syndrome, activity related<br>Aphthous stomatitis, 10% activity related |
| Ocular | Scleritis or episcleritis, 2%-3%, activity related<br>Uveitis, 2%-6% |
| Hepatobiliary | Primary sclerosing cholangitis, as many as 7%<br>Acute pancreatitis |
| Thromboembolic | Both venous and arterial, 1%-6%, activity related |

On the basis of examination of approximately 1500 patients with IBD, an important distinction was made between two forms of peripheral arthritis[58] (Figure 78-9). Oligoarthritis, or type I, affects fewer than five joints, whereas polyarthritis, or type II, involves more than five joints. The highest prevalence was found in metacarpophalangeal, proximal interphalangeal, knee, and ankle joints. Shoulder involvement was more common in UC, but joint involvement was otherwise strikingly similar. The majority of type I arthritis cases were acute and resolved within 6 weeks, whereas the type II cases persisted.[59] Type I arthritis was 12 times more prevalent in carriers of the rare *HLA-DRB1**0103 allele, type II arthritis was associated with HLA-B44, and sacroiliitis in CD was associated with *NOD2* polymorphisms.[60] This is an example of genetic influence on disease phenotype and may be a clue to pathogenesis.

Clubbing of fingers, uveitis, and skin manifestations are other extraintestinal manifestations of IBD, with a higher frequency in patients with CD. Erythema nodosum, which is usually self-limited, is most frequent in young female patients with UC. Pyoderma gangrenosum is a more severe, painful, ulcerating skin reaction that is frequently associated with systemic disease[61] (Figure 78-10). In a series of 86 patients with pyoderma gangrenosum seen at the Mayo Clinic between 1970 and 1983, 31 patients had IBD.[7] Erythema nodosum, uveitis, and peripheral arthritis commonly occur together in IBD and have been linked to *HLA-DRB1**0103 and *TNF* gene polymorphism.[62] Uveitis is also a feature of other forms of spondyloarthritis, such as AS and reactive arthritis. In IBD, however, uveitis is more often bilateral and more prone to chronicity.[63,64] Primary sclerosing cholangitis (PSC), a progressive liver disease that can lead to end-stage liver fibrosis, can develop in as many as 5% of the patients with UC and CD. The risk for colorectal cancer is increased in IBD and is related to the extent of colonic involvement and disease duration. Colorectal cancer mortality has decreased significantly in the past few decades, mainly because of better surveillance and earlier diagnosis.[67,68]

## Diagnosis

| KEY POINTS |
|---|
| MRI in cases of suspected inflammatory back pain is recommended. |
| Fecal calprotectin is a useful screening test for inflammatory bowel disease. |
| Large joint oligoarthritis may mimic reactive arthritis. |
| Monogenic inflammatory bowel disease-like disease has been reported in children. |

In young children, very rare instances of monogenic IBD-like disease, for instance, with IL-10 mutations, have been identified.[69] These conditions are often combined with peripheral arthritis, typically familial, and their study can be informative to understand the pathogenesis of the classic genetically complex forms of IBD. No specific tests exist to confirm a suspicion of IBD-related arthritis. Careful history and clinical examination remain the principal diagnostic tools. Arthropathy can precede intestinal symptoms in a subgroup of patients, and thus colonoscopy with histologic exploration can be informative regarding the origin of occurring joint symptoms. When inflammatory back pain is suspected, MRI of the sacroiliac joints is mandatory.[70] Fecal calprotectin has emerged as a sensitive screening test for IBD, and it helps to select cases for endoscopic exploration.[65] As mentioned earlier, genetic mapping has shown interesting clinical correlates, but genotyping is not part of the routine clinical workup, except perhaps for HLA-B27. Stool cultures should be performed when infection with special pathogens is suspected. In patients with apparent IBD and monoarthritis, joint aspiration is important to exclude septic arthritis, especially before immunosuppressive therapy is begun.

## Treatment

| KEY POINTS |
|---|
| Arthralgia is common in inflammatory bowel disease. |
| NSAIDs should be avoided. |
| "Nonradiographic" spondyloarthritis can precede intestinal symptoms. |
| Early treatment with TNF inhibitors can potentially prevent spinal destruction. |
| Patients with inflammatory bowel disease are at higher risk for complications after total hip replacement. |
| The efficacy of probiotics remains unproven. |

Management of musculoskeletal IBD requires awareness of other EIMs. Ocular, cutaneous, and hepatic manifestations are most prevalent, but pulmonary and neurologic manifestations also need attention. Arthralgias are by far the most common peripheral arthritis complaint, but because of increased risk of exacerbation of intestinal disease NSAIDs should be avoided. Type I peripheral arthritis, that is, a large joint oligoarthritis, has features of reactive arthritis coinciding with intestinal activity. It is usually self-limiting, may remit, and requires symptomatic treatment, for instance, with intra-articular glucocorticoids.

Spondyloarthritis, with or without polyarticular type II polyarthritis, is a more severe manifestation. When inflammatory back pain is suspected, MRI of the sacroiliac joints is mandatory. If positive, treatment with a biologic agent may be indicated.

Several randomized trials have shown efficacy in treating IBD with monoclonal anti-TNF antibodies.[71-76] Only one small trial of etanercept was negative. The reason remains unknown. Inhibition of TNF is also effective against spondyloarthropathies with IBD. Treatment should be started early to prevent or delay structural damage to the spine.[77]

Vedolizumab is an all human monoclonal antibody against the $\alpha_4\beta_7$ integrin receptor involved in gut homing of T cells. Based on a few positive phase III trials, it has been approved for the therapy of UC and CD. Efficacy in IBD-related spondyloarthritis is not known. Inhibition of the IL-12/IL-23 pathway using IL-17 inhibitors secukinumab and brodalumab failed in treatment of patients with CD, whereas ustekinumab had an effect in patients with CD in whom treatment with TNF inhibitors failed. Development of an IFN-$\gamma$ inhibitor, fontolizumab, as well as abatacept, seems ineffective.[78]

Probiotics, although theoretically attractive, have not been found to be effective in treating CD, and are of unconfirmed limited efficacy in UC.[79] Their safety remains to be documented.[80] Azathioprine and glucocorticoids used in intestinal IBD could be beneficial against arthritis, but no controlled trials have been done. Azathioprine has been widely used to maintain remission in IBD. It has proven long-term efficacy in both UC-related colitis and CD, according to a large European study.[71] It should not be combined with 5-aminosalicylic acid, because of a pharmacokinetic interaction.[72] Destructive hip disease may require total joint replacement. Patients with IBD are at higher risk of infection and need of revision.

## Outcome

The outcome of type I peripheral arthritis is linked to bowel activity, but it is generally benign. Type II peripheral arthritis is erosive and progresses independently of disease activity in the gut. The outcome of IBD-associated spondyloarthritis is considered to be similar to that of spondyloarthritis in general. Information on the effects on musculoskeletal involvement of the biologics is incomplete. A Swedish study shows higher survival among male patients with peripheral arthritis who are on drug therapy.[81]

# *BRUCELLA* ARTHRITIS

| KEY POINTS |
|---|
| Brucellosis is a leading zoonosis in the Middle East. |
| Brucellosis is rampant in developing countries as a consequence of urbanization. |
| Stray dogs and unpasteurized cattle food consumption spread the infection. |

### Epidemiology

Some years ago, there was hope that brucellosis would soon be extinguished. However, an estimated half million new cases occur annually worldwide and make it a leading zoonosis and a common cause of musculoskeletal problems in endemic areas, where the incidence may reach 200 cases per 100,000 of the population.[82] It is the dominating zoonosis in some African and Middle East countries, but high prevalence is also seen in India and other parts of Asia. Traditionally, brucellosis was a rural disease, affecting people working with infected cattle or consuming unpasteurized dairy products.[83-85] However increasing prevalence has been observed in big cities in China, usually caused by consumption of dairy products or raw meet.[86] In the Western world travelers can import brucellosis. Urbanization and widespread infection in sheep, cattle, and perhaps also in small ruminants constitutes an increasing threat in Nigeria and many sub-Saharan countries as well as in China.[86]

### Etiology and Pathogenesis

Sheep- and goat-derived *Brucella melitensis* is the dominating infecting species. Ten members of the genus *Brucella* are known. *Brucella abortus* from cattle and *Brucella suis* from swine are unusual causes of human disease, whereas *Brucella melitensis* dominates because of the less effective eradication of animal reservoirs among sheep and goat. *Brucella canis* from stray or domesticated dogs is rare in humans.[82] The small Gram-negative organisms enter GI mucosa and survive in macrophages, migrating to lymph nodes where they multiply and spread to the circulation.

### Clinical Features and Diagnosis

Brucellosis causes arthritis in approximately one-third of cases. The main locations are the spine in adults and the peripheral joints in children and adolescents. Knees, hips, and ankles are the dominant peripheral locations. Sacroiliitis can be extremely acute and painful. Rising titers of serum antibodies and a confirmatory culture solidify the diagnosis. Case reports describe septic prepatellar bursitis[84] and olecranon bursitis[85] and indicate that fluid from these lesions can be diagnostic. Several serologic and polymerase chain reaction (PCR) tests are available. Blood cultures prove a septic state, whereas synovial cultures rarely are positive.[82]

### Treatment and Outcome

The World Health Organization guidelines for treatment include using doxycycline (100 mg p.o. twice a day) for six weeks, in combination with either streptomycin (1 g i.m. once a day) for two to three weeks or rifampin (600-900 mg p.o. once a day) for six weeks. The former regimen is thought to be more effective by some investigators. As with all regimens, the clinical circumstances of the patient could require a change in dose or duration of therapy.[86a] The arthritis can become destructive unless treated early. Spinal stenosis may be a complication.

## BOWEL-ASSOCIATED DERMATOSIS-ARTHRITIS SYNDROME

**KEY POINTS**

- BADAS develops as a consequence of bacterial overgrowth.
- BADAS responds to anti-microbial therapy.

### Epidemiology

Bowel-associated dermatitis-arthritis syndrome (BADAS) was discovered in the 1970s as "bypass arthritis" and later renamed because the syndrome was also seen without bypass surgery. The prevalence is not known, but originally it was reported in as many as 20% of patients after abdominal surgery. Newer surgical techniques have decreased the risk some, but awareness remains important in patients with impaired bowel function, including IBD and less common conditions (e.g., short bowel syndrome and systemic sclerosis).[87,88]

### Etiology and Pathogenesis

BADAS by definition is caused by disturbances in the GI canal. It can occur after all kinds of GI surgery. The supposed mechanism is dysbiosis often secondary to disturbed peristalsis or blind loop created by surgery or intestinal disease. Absorbed microbial products result in neutrophile dermatoses, which can be oral aphthous ulcers, pustular skin lesions, erythema nodosum, or pyoderma gangrenosum.[89] Recurrent arthritis, predominantly in the legs, arthralgia, and episodes of fever, indicate the systemic nature of BADAS. The molecular mechanisms have not been characterized. Bacterial overgrowth and neutrophil accumulation is present, and a role for immune complexes caused by absorbed microbial products has been postulated.[89]

### Clinical Features and Diagnosis

The main features seen in patients in the 1970s were an intensely painful oligoarthritis of large and small joints and spine, without structural changes, and a recurrent papulopustular rash (Figure 78-11). Tendinitis and enthesitis is another feature. Recurrent episodes of exacerbated skin and

**Figure 78-11** Relapsing pustulosis in a patient with bypass arthritis-dermatitis.

musculoskeletal manifestations may become chronic or disappear spontaneously.

### Treatment and Outcome

Antibiotic therapy with metronidazole, neomycin, or minocycline can be effective. Symptomatic therapy with local glucocorticoids or, sometimes, oral glucocorticoids can be used. Overtreatment should be avoided because the outcome is usually benign. Physical health and mobility is often improved following successful bariatric surgery.

## CELIAC DISEASE

| KEY POINTS |
|---|
| Adult CeD affects about 1% of the population and diagnosis is often delayed. |
| CeD is more common in women. |
| HLA-DQ2 or DQ8 confers susceptibility, with an odds ratio (OR) of 10. |
| Gluten triggers and maintains CeD. |
| Sensitivity to gliadin, endomysium A, and tissue transglutaminase are the causal factors. |
| Nonspecific symptoms cause delayed diagnosis. |
| Arthralgia and arthritis can be the initial symptoms. |
| A gluten-free diet is the only effective therapy. |

### Epidemiology

CeD is emerging as a common but underdiagnosed condition. It used to be considered a disease of Caucasians in Western countries, but now CeD occurs globally and in all ethnic groups.[90] The reported prevalence of 1% in adults may be an underestimate.[91] CeD is more common in women.[92] CeD has been found in 6% of patients with idiopathic juvenile arthritis.[92]

### Genetics

The association of CeD with HLA-DQ2 was discovered 30 years ago. To be susceptible, an individual must carry HLA-DQ2 or DQ8. This explains 40% of genetic susceptibility and confers an OR of more than 10. GWAS analysis has revealed 40 non–HLA-associated SNP polymorphisms with ORs less than 2.[91] As expected, several of the associations are shared with other immune-regulated diseases. Taken together, the replicated associations only explain 5% to 10% of CeDs heritability.[93,94]

### Etiology and Pathogenesis

Gluten intolerance and immunization against the identified antigens gliadin, endomysium A, and tissue transglutaminase explain much of the pathogenesis of CeD. It was shown in 2002 that dietary gluten is partly digested by gastric enzymes to generate a stable 33–amino-acid peptide that is deamidated by tissue transglutaminase.[95] The peptide is then presented in the context of HLA-DQ2 or HLA-DQ8 to $CD4^+$ T cells, resulting in IFN-γ release and inflammation. Early presence of impaired endothelial integrity[95] confirms the importance of a defect of the mucosal barrier. Villus atrophy is the end result. Malabsorption and systemic features from the skin, the endocrine glands, and the musculoskeletal system follow.

### Clinical Features and Diagnosis

Diarrhea and sprue symptoms are the classic symptoms, but patients with CeD more often present with atypical abdominal pain, nonspecific fatigue, headache, and arthralgia.[92] Correct diagnosis is often delayed for 10 or more years. CeD is a systemic disease involving type 1 diabetes, anemia, osteoporosis, neuropathies, and joint symptoms in as many as 25% of patients.[97] Asymmetric oligoarthritis or polyarthritis and axial involvement are common. Arthritis can be the presenting symptom of the disease.[98]

A small bowel biopsy showing atrophic villi is diagnostic, and serum for IgA anti–tissue transglutaminase antibodies and IgA antiendomysial antibodies are present in 95% of patients and confirms the diagnosis.[95]

### Treatment and Outcome

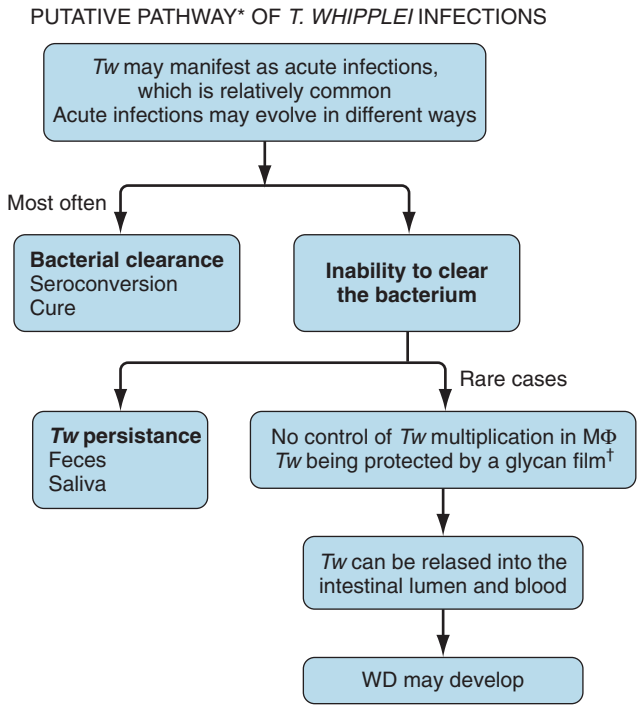
Elimination of gluten from the diet is the rational therapy, and is often the only one required. In addition, various experimental approaches have been discussed but are not yet supported by data. These include the administration of IL-10 to boost regulatory T cells, the induction of tolerance by nasal application of gluten peptides, and gene therapy.[99] No specific therapy has been established for the joint problems. Osteomalacia may require administration of vitamin D.

Children with verified CeD still have abnormal mucosa in adulthood and must continue the dietary restriction.[100]

## WHIPPLE'S DISEASE

| KEY POINTS |
|---|
| Anti–*Tropheryma whipplei* serology is found in 50% to 70% of adults. |
| Acute *T. whipplei* gastroenteritis outbreaks occur. |
| *T. whipplei* is transmitted by oral-oral and fecal-oral contact. |
| Asymptomatic carriage is the rule. |
| Restricted immune deficiency may be the cause of classic Whipple's disease. |
| Immune histology of gut biopsy establishes the diagnosis, and real-time PCR of saliva supports it. |
| Doxycycline and hydroxychloroquine is preferred versus trimethoprim-sulfamethoxazole. |

### Epidemiology



The discovery of *Tropheryma whipplei* in 1992, followed by the development of sensitive and reliable assays, have revealed that in contrast to the very rare classic Whipple's disease, infection with *T. whipplei* is extremely common in humans. The pathogen has been identified in sewers but no

animal reservoir is identified. The infection is spread by oral-oral and fecal-oral contact and is therefore more prevalent in populations with poor hygiene. Carriage is endemic among sewer workers. Positive serology is present in 50% to 70% of adult populations.[102] Acute outbreaks of gastroenteritis have been linked to the organism. The incidence and prevalence of classic Whipple's disease are unknown, but some clustering (e.g., in eastern parts of France) has been observed.

## Genetics and Pathogenesis

George Hoyt Whipple (1878-1976), an American pathologist, published the case of a 36-year-old white medical missionary with migratory polyarthritis, cough, diarrhea, weight loss, malabsorption, and mesenteric lymphadenopathy in 1907. Dr. Whipple observed "great numbers of a rod-shaped organism" in a lymph node.[102] In 1992, the nature of the organism as a Gram-positive actinomycete was finally identified with the bacterial 16S microRNA technique.[103] Five years later, Swiss investigators succeeded in culturing *T. whipplei* in deactivated human macrophages.[104] Classic Whipple's disease, originally named *intestinal lipodystrophy*, is rare, but 2% to 13% of Europeans carry live *T. whipplei* in their stool. The initial infection may be silent or manifest as an acute infection, which usually resolves but causes seroconversion. In a minority of the infected, the bacteria will not be cleared, resulting in an asymptomatic carrier state.[105,106] Then, for some unknown reason, the organisms begin to replicate inside macrophages, and cause the rare classic disease (Figure 78-12). In a cohort of 122 European patients, an association between the HLA alleles *DRB1*13* and *DQB1*06* and Whipple's disease was found, supporting a genetic contribution to susceptibility.[107]

Six different genotypes have been confirmed in cultures from diseased tissue.[108] Reinfection with different strains indicates that immunodeficiency restricted to *T. whipplei* with the inability to produce an adequate T cell response exists in some individuals.[102] The organism lives in macrophages, and these elicit a skewed lymphocyte response, with suppressed Th1 dominating Th2 cells. Expression of the cytokine IL-16 stimulates growth of the pathogen.[105] In vitro monocytes from patients with Whipple's disease express CD163, possibly explaining a reduced oxidative impact against *T. whipplei*.[106]

*This pathway is incomplete but this is the way the authors see the progression of the disease.

†Bonhomme CJ, Renesto P, Desnues B, et al: *Tropheryma whipplei* glycosylation in the pathophysiologic profile of Whipple's disease. *J Infect Dis.* 199:1043-1052, 2009.

**Figure 78-12** *Triphyroma whipplei* (TW) infection and its development into Whipple's disease. *(From Fenollar F, Lagier JC, Raoult D:* Tropheryma whipplei *and Whipple's disease.* J Infect Dis *69:103-112, 2014.)*

## Clinical Features

The disease can have many faces and may remain undiagnosed for decades. A correlation between different clinical manifestations and variable genotypes of the bacterium has not been identified, and host factors seem to be crucial for the kind of manifestation.[107] Altered gut permeability may be a factor in joint involvement. Dominating features can consist of recurrent fever, malaise, hematologic, pulmonary, cardiac disturbances, neurologic, or ophthalmic symptoms. Articular symptoms, however, are present early in two-thirds of cases, whereas intestinal symptoms are initially seen in only 15%. With time, diarrhea, abdominal pain, and malnutrition develop in 83% of patients. Arthralgia and arthritis are most frequent in knee joints but can localize in any peripheral joint, as well as in spinal joints and disks. Sacroiliitis has been described.

## Diagnosis

Immune histology, with the occurrence of periodic acid–Schiff–positive material, an abundance of $CD68^+$ macrophages, and staining with antisera specific for *T. whipplei* establishes the diagnosis. Real-time PCR serology of saliva and stool support the diagnosis.[109] PCR of cerebrospinal fluid can detect central nervous system involvement. The organism can grow out in culture, which takes an average of 30 days. In one study, only 2 of 10 small bowel specimens were culture positive; the yield is higher with sterile cardiac or nerve tissue.[104] Culture, however, remains a research tool.

## Treatment

The efficacy of oral trimethoprim-sulfamethoxazole is controversial. The recommended treatment consists instead of 12 months administration of doxycycline, 200 mg, combined with hydroxychloroquine, followed by life long prophylactic doxycycline.[102]

## Outcome

Without treatment, Whipple's disease is chronic or relapsing, usually progressive, and ultimately fatal. With adequate antibiotic therapy, clinical remission is usually complete or near complete.

## MICROSCOPIC COLITIS

Microscopic colitis (MC) is a name given to two conditions that present with profuse diarrhea. The first, collagenous colitis (CC), was described in 1976 and the second, lymphocytic colitis (LC), in 1989. A rare third condition, collagenous gastritis (CG), was described in 2009. Its frequent association with arthritis, arthralgia, diabetes, and thyroid disease motivates the inclusion in this chapter.[110]

### Epidemiology

Although initially considered rare, it is now evident that MC is a common cause of watery diarrhea in several populations, with an annual incidence of 5 to 6/10,000 for CC and for LC. It is 5 to 10 times more common in individuals older than 65 years and distinctly more common in women.[100] The female-to-male ratio is 7 : 1 in CC and 2 : 1 in CC. The peak incidence is seen in patients 60 to 80 years old. The total prevalence of 100 to 200/100,000 makes MC a common condition.[110]

### Etiology

Environmental factors in association with genetic susceptibility are involved. Smoking is an important contributing factor, and MC develops in smokers an average of 10 years earlier than in nonsmokers. MC is associated with *HLA-DQ2* or *DQ1,3*, the *HLA-DR3-DQ2* haplotype, and the *TNF2* allele, regardless of the presence of concomitant CeD.[110] Drug exposure is a likely trigger and may in part explain some disease associations. Drugs that are prime suspects include acarbose, aspirin and NSAIDs, proton-pump inhibitors (in particular lansoprazole), ranitidine, sertraline, and ticlopidine.[111] CC, LC, and CG all seem to be associated with CeD, autoimmune thyroid disease, and arthritis, presumably secondary to dysbiosis and abnormal GALT signaling.

### Pathogenesis

No infectious agent has been identified. Luminal factors are strongly suggested by the almost complete histologic normalization in patients after ileostomy is performed, and the recurrence of pathology and symptoms after its closure.[116] Connective tissue growth factor was markedly increased in the subepithelial zone of biopsies from CC patients analyzed by reverse transcription PCR, indicating a pathogenic role for connective tissue growth factor (CTGF).[117] Imbalance between matrix metalloproteinases (MMPs) and tissue inhibitors of MMP (TIMP) and activation of myofibroblasts may contribute to the pathogenesis of CC. Abnormal cytokine signaling has been observed in LC,[112] and increased IL-17 signaling has been identified.[113]

### Clinical Features

Chronic and intermittent (or sometimes chronic and persistent) painful and watery stools, weight loss, and fatigue are the cardinal intestinal symptoms. There is no difference between collagenous and lymphocytic colitis in this regard. The course is acute or chronic but usually benign.

Autoimmune conditions are seen in 30% to 50% of MC cases.[110] These include rare cases of systemic lupus erythematosus (SLE) and scleroderma, Sjögren's syndrome, nondestructive oligoarthritis, migratory arthralgias, sacroiliitis, and rheumatoid arthritis.

### Diagnosis

The diagnosis can be made only by histology obtained with colonoscopy. Endoscopic examination is essentially normal. The Malmö pathologist Claes Lindström found a characteristic thickening of the collagen layer under the gut epithelium. This layer is normally 3 μm, but in CC, it is more than 10 μm and may reach 50 to 100 μm (Figure 78-13). In addition, one can see inflammation and an increased number of lymphocytes. The histology of LC shows an abundance of epithelial lymphocytes (Figure 78-14). In both conditions, the gut epithelium remains intact, although colonic mucosal tears are occasionally present.[116]

### Treatment and Outcome

Any suspected harmful drugs should be eliminated. The presence of CeD should be considered. Initial antidiarrheal therapy consists of 2 to 16 mg of loperamide and cholestyramine, 4 g/day. Bismuth subsalicylate is recommended.

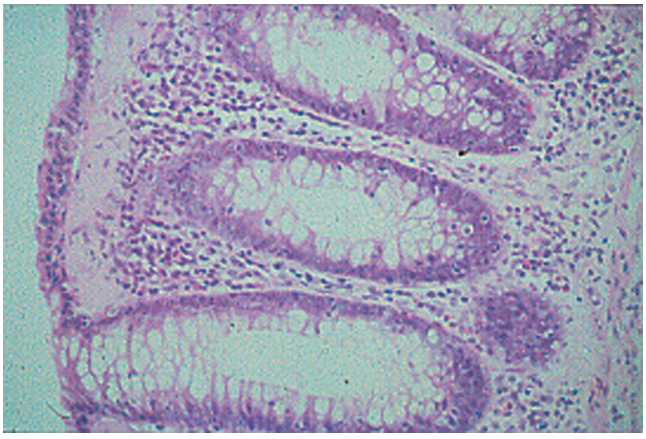


**Figure 78-13** Collagenous colitis. Note the intact epithelium and massive subepithelial collagen layer. *(Courtesy Dr. Claes Lindström.)*

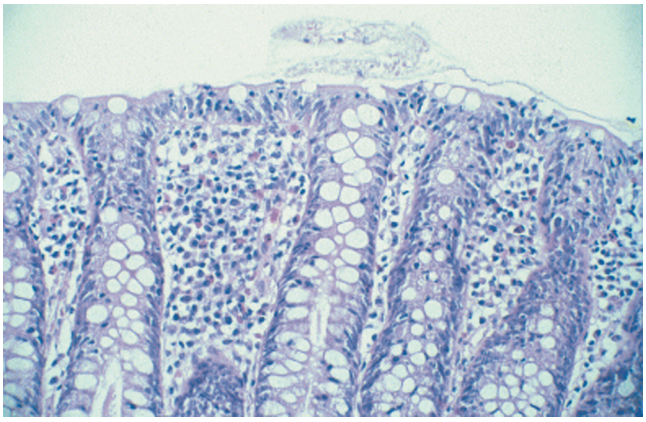

**Figure 78-14** Lymphocytic colitis. Note the epithelial lesions with intraepithelial lymphocytosis and inflammation of the lamina propria. *(From Wollheim FA: Collagenous colitis and rheumatology.* Curr Rheumatol Rep *2:183–184, 2000.)*

Budesonide, 9 mg/day, induces remission in at least 80% of patients, but relapse of diarrhea is common after the treatment is ended. When severe symptoms persist, TNF inhibitors, azathioprine, and even temporary ileostomy may be effective. The long-term prognosis is good, although arthralgia and other symptoms may persist for years.[114]

## PONCET'S DISEASE AND BACILLE CALMETTE-GUÉRIN–INDUCED ARTHRITIS

In 1897 the famous French professor of surgery in Lyon, Antonin Poncet published his paper "*La polyarthrite tuberculeuse simulant des lésions rhumatismales chroniques déformantes*," in which he described a patient with tuberculosis and arthritis without signs of local presence of tubercle bacillus. Similar cases have been identified during the years in children and adults with a diagnosis of tuberculosis and, more recently, in patients treated with bacille Calmette-Guérin (BCG) vaccine to stimulate immunity to malignant diseases. The existence of Poncet's disease (PD) remains controversial because it is rare and often a diagnosis of exclusion. The global surge of tuberculosis, with 10 million new cases per year, motivates a higher awareness of possible musculoskeletal manifestations.[118,119]

### Epidemiology

An extensive search of the literature identified 199 published case reports of PD. The following numbers of cases of PD have been reported globally: India, 70 cases; Brazil, 36 cases; Mexico, 20 cases; the United Kingdom, 12 cases; Nigeria, 6 cases; in Russia, Spain, the United States, and Pakistan, 5 cases; Iran, 4 cases; and in Japan, Korea, and France, 3 cases in each country.[120] One or two cases were published from several other countries. The incidence of BCG-induced cases is unknown, but is probably very low.

### Etiology and Pathogenesis

The vast majority of musculoskeletal manifestations of tuberculosis are of a septic nature. Active tuberculosis, or the administration of BCG, also can elicit nonseptic arthralgia and benign arthritis, which by definition is reactive. The enteropathic nature is not firmly established. HLA-B27 may be a susceptibility factor in post-BCG arthritis.[7] *Mycobacterium* heat shock protein 65 has been implicated in both of these sterile forms of arthritis, as well as in others.[121] Mycobacterial and human heat shock proteins are 50% homologous, and one hypothesis is that both the therapeutic efficacy and the arthritis are caused by cross-reactive T lymphocytes. Heat shock protein also has homologies with proteoglycan and HLA-DR. The pathogenesis of arthritis after intravesical instillation of BCG might be different and related to antigen persistence.

### Clinical Features and Diagnosis

PD is most often seen in younger adults of both sexes. Onset is insidious with fever, arthralgia, and malaise. Knee joints and ankles, followed by elbows and wrists, are the most common arthritis localizations. In contrast to septic tuberculosis arthritis, the condition is nondestructive. Several authors report rapid improvement upon therapy against tuberculosis.

The diagnosis is based on the clinical findings, presence, or a history of active tuberculosis, and exclusion of other causes of arthritis.

### Treatment and Outcome

Post-BCG cases usually heal without treatment within 3 months. Although culture results are negative, it is common practice to treat for 4 to 6 months with conventional antituberculosis therapy.[122] The positive outcome associated with this practice hints at sensitivity to bacterial elements.

## ENTEROVIRAL AND HEPATITIS VIRUS–ASSOCIATED ARTHRITIS

### Epidemiology

*Enterovirus* infections, similar to other common virus infections, often give rise to arthralgias.[123] The precise prevalence is not known. Hepatitis B and hepatitis C virus (HCV) infection causes joint manifestations in 2% to 38% of cases.[124] Considering that HCV infection alone causes 3 to 4 million new cases each year, this is not a trivial problem.[125]

### Genetics and Pathogenesis

No genetic factors have been identified. *Enterovirus* species can invade joints and may rarely be isolated from joint fluid.[126] Immune complex–mediated activation may result in viral hepatitis. A preferential deposition of such immune complexes in joints results in arthralgias and arthritis. In hepatitis C disease, precipitation of cryoglobulins is often observed. Molecular mimicry has been proposed but not proved. Viral persistence in host cells with continuous production of viral protein expressed on cell surfaces has been observed.[127] Immunosuppressive therapy may reactivate latent virus growth, and may be misinterpreted as increased disease activity in patients with other rheumatologic conditions.

### Clinical Features

Hepatitis B may be associated with a variety of general symptoms, including fever, abdominal pain, nausea, and vomiting after a prodromal period of as long as 6 months. Articular symptoms also develop in 10% to 25% of these patients, symptoms that may present during the prodromal phase. The preferential locations are hands and knees. In addition to morning stiffness, migratory arthritis is common. Interestingly, a coincident appearance of urticaria-like rash, predominantly of the legs, is common. The arthritis characteristically disappears with the onset of jaundice.[128]

A chronic disease with persistent or remitting articular manifestations develops in less than 5% of hepatitis B–infected individuals. The disease is self-limited, and requires only symptomatic treatment.[126]

HCV is associated with joint symptoms in 20% of cases. Other frequent symptoms are myalgia, glomerulonephritis, and vasculitis or essential mixed cryoglobulinemia, which may become severe. Oligoarthritis occurs in one-third of the cases, whereas polyarticular disease develops in two-thirds of cases.[129] The early symptoms can mimic RA. RF may be positive in as many as 80% of patients, whereas anti-citrullinated protein antibody (ACPA) only occurs in 4% to 7% of cases. Another mimic is SLE. HVC is among the suspected triggers of SLE.[125]

Enteroviruses, coxsackie viruses, and echoviruses are only associated with arthropathy in less than 1% of cases, but because of the high prevalence of the primary disease, the number of arthritis cases is not trivial.[129] After an incubation period of 3 to 5 days, the patients experience fever, fatigue, headache, pharyngitis, myalgia, rash, pleuritic pain, and conjunctivitis or, alternatively, nausea, abdominal pain, enteric cramps, vomiting, and diarrhea. Joint symptoms are self-limited and disappear within days, although recurrence can occur. Any peripheral joint may be affected.

CHAPTER 79

# Etiology and Pathogenesis of Systemic Lupus Erythematosus

Mary K. Crow

## KEY POINTS

- Systemic lupus erythematosus (SLE) results from chronic and recurrent activation of the immune system, with production of antibodies and other protein products contributing to inflammation and tissue damage.
- SLE is most common in females and typically begins in the childbearing years. This suggests a role for both hormones and as yet uncharacterized sex-related factors in disease pathogenesis.
- Progress in genetic analysis has resulted in identification of genetic variants associated with SLE, with most related to innate and adaptive immune system function. Complement deficiencies confer the highest risk of disease. Mutations or common variants in genes that encode components of the endosomal Toll-like receptor pathway or regulators of endogenous nucleic acids contribute to innate immune system activation.
- Environmental factors contribute to initiation of lupus and lupus flares.
- A contribution of nucleic acid–containing immune complexes as stimuli for endosomal Toll-like receptors has added an important new role for immune complexes in the pathogenesis of SLE.
- Production of type I interferon (IFN), broad expression of type I IFN–inducible genes, and the effects of IFN on immune system activation and function have emerged as central mechanisms of lupus pathogenesis.
- T cell subsets, including T follicular helper cells, cytokines, and soluble survival factors such as B lymphocyte stimulator (BLyS) promote B cell differentiation and autoantibody production.
- Platelets and neutrophils, along with neutrophil extra-cellular material, have gained new attention as important pathogenic effectors. Complement remains an important mediator of inflammation.

Systemic lupus erythematosus (SLE) is one of the most widely studied diseases in medicine. Predominantly a disease of young women in their childbearing years, and with the potential to cause significant physical disfigurement, morbidity, and, occasionally, mortality, lupus is the focus of strong advocacy to support research that will generate insights into disease pathogenesis. In fact, characterization of the immunologic contributors to lupus, the prototype systemic autoimmune disease, has been the focus of particularly intense study since the flowering of the discipline of immunology in the 1950s and 1960s. Recent efforts to define the genetic variations that underlie susceptibility to lupus have supported the central role of the immune system in disease pathogenesis, but have extended the view of lupus pathology beyond the important role of autoantibodies and T cells to include a significant contribution of the innate immune system to disease. An underlying role for the vasculature as a target of the immune system and its products is gaining renewed interest as an important component of lupus pathogenesis. Together, these recent advances provide important insights into how the intersection of genetic variations with environmental triggers amplifies immune system activation and target organ vulnerability to generate the classic manifestations of lupus and its clinically significant comorbidities. Figure 79-1 provides a schematic overview of many of the contributors to SLE and how their interactions drive autoimmunity and tissue damage.

## HISTORIC VIEW OF LUPUS PATHOGENESIS

Insights into the immunopathogenic mechanisms that account for development of autoimmunity in patients with SLE and the tissue damage that results in disease have occurred periodically during many decades. Progress has been informed by the scientific tools available at the time, along with the acute observations of clinicians and research scientists. Descriptions of the clinical manifestations of disease have suggested a multisystem disease that typically involves skin and joints, with renal, cardiac, and neurologic pathology suspected and then documented with histologic studies. Alterations of blood vessels in many organs were recognized as an important component of the disease process in early studies, with the pathognomonic "onion skinning" of splenic arterioles, cellular infiltration and damage to renal glomeruli, and vasculopathy in skin and brain demonstrated clinically by manifestations such as nephritis, livedo reticularis, and stroke. The lupus erythematosus (LE) cell, described by Hargraves in 1948, suggested that engulfment of cellular debris, a mechanism that remains an important concept in considerations of lupus pathogenesis, was active at sites of inflammation.

The recognition that antibodies directed at cellular components, particularly cell nuclei, were present in the

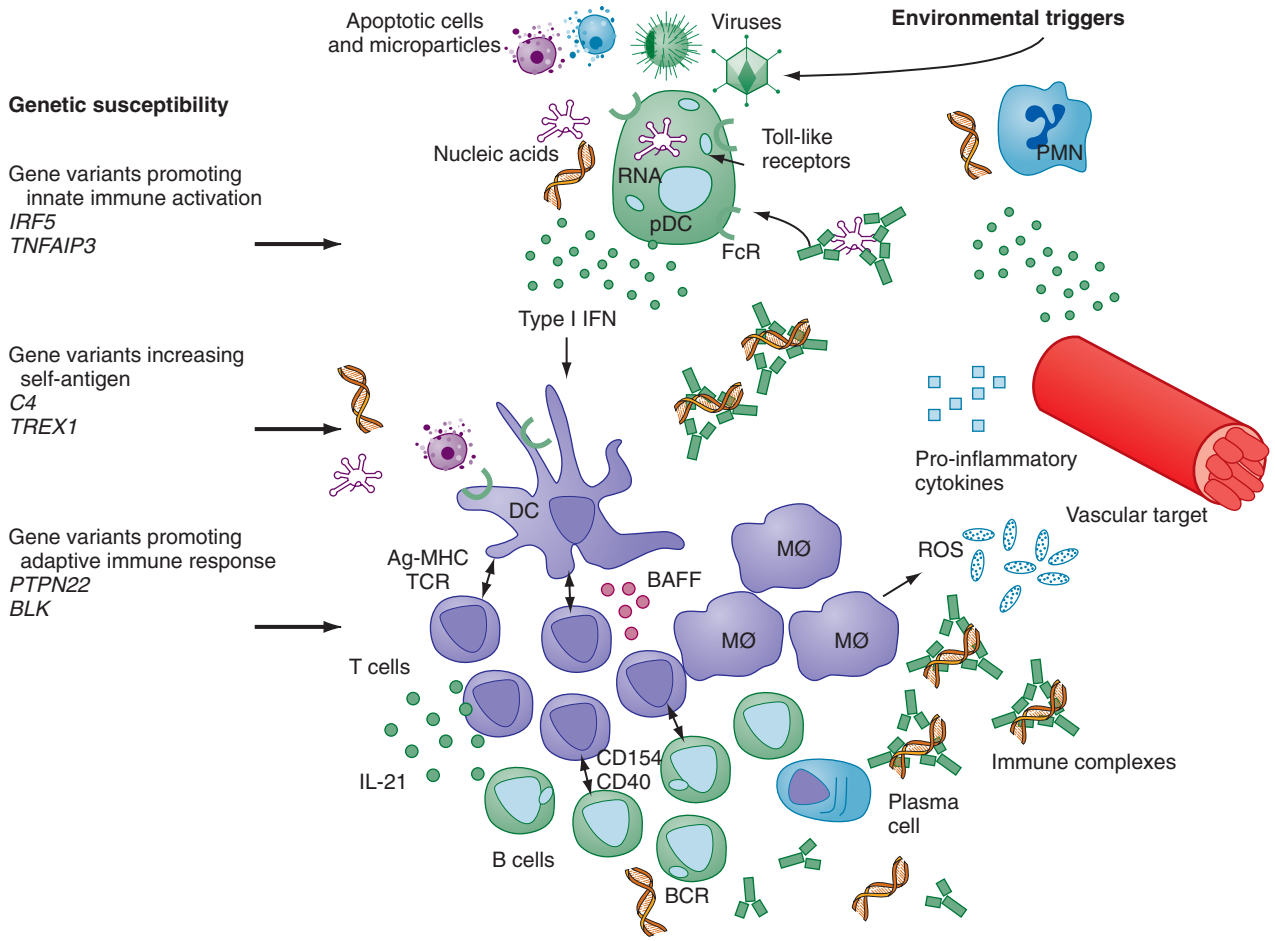

**Figure 79-1** Contributors to systemic lupus erythematosus (SLE) pathogenesis. Mechanisms that promote development of SLE are related to the underlying genetic profile of the individual. Many of the disease-associated genetic variants (examples are illustrated) contribute to excessive production or impaired clearance of stimulatory nucleic acids; increased generation of products of the innate immune response, particularly type I interferon (IFN); or an altered threshold for activation or efficiency of signaling of cells of the adaptive immune response. In most cases, multiple genetic risk variants are required to establish a state of immune activation that is receptive to environmental triggers that promote development of autoimmunity. In rare cases, a mutation of a critical regulator of immune activation can be sufficient to initiate the altered immune state that can lead to disease. IFN is a product of plasmacytoid dendritic cells (pDCs). Activation of the cells by intra-cellular nucleic acids or exogenous triggers, such as a virus or debris derived from damaged or dying cells, might represent mechanisms of initiation of disease. Once IFN-α is produced, it mediates numerous effects on immune system cells that mimic the response to a viral infection. The antigen-presenting capacity of myeloid dendritic cells can be augmented, promoting activation of self-reactive T cells and differentiation of B cells toward production of pathogenic antibodies. Activated T cells express CD154 (CD40 ligand) and produce interleukin-21 (IL-21), providing effective help for B cells to generate antibody-producing plasma cells. IFN-α also supports the production of B cell–activating factor (BAFF, also known as B lymphocyte stimulator), a survival and differentiation factor for B cells. Once autoantibodies are produced, immune complexes amplify immune activation by accessing endosomal Toll-like receptors in pDCs and B cells and depositing them directly in the vicinity of blood vessels, inducing complement activation, inflammation, and tissue damage. Reactive oxygen species (ROS) and pro-inflammatory cytokines produced by monocytes and macrophages contribute to tissue damage, as does IFN-α, which stimulates endothelial cells and is associated with poor vascular repair and sclerosis. Ag-MHC, Antigen–major histocompatibility complex; BCR, B cell receptor; DC, dendritic cell; FcR, Fc receptor; MØ, macrophage; PMN, polymorphonuclear neutrophil; TCR, T cell receptor.

sera of patients with SLE directed the attention of researchers toward the immune system. The conclusion was reached that lupus reflected an autoimmune process. Pathologic studies of kidneys from patients with lupus nephritis showing glomerular deposition of immunoglobulin and complement components, combined with the elution of anti-DNA autoantibodies from lupus kidneys, contributed to the concept that autoantibodies, particularly anti-DNA antibodies, were pathogenic. Isolation from lupus sera of complexes of antibody with DNA or DNA-binding proteins, such as histones, was an important factor in the classification of SLE as predominantly an immune complex-mediated autoimmune disease. Although lupus pathogenesis does depend on those immune complexes and the inflammatory responses that they induce, subsequent investigation identified virtually all cell components and many soluble immune system products as contributors to the immune system dysfunction that ultimately accounts for disease in SLE.

The development of the field of cellular immunology in the 1970s and the later identification of the T cell antigen receptor, along with families of co-stimulatory molecules that mediate interactions between T cells and antigen-presenting cells or B cells, led to the implication of self-reactive T cells as important regulators of immune responses, as well as helpers for B cell differentiation to autoantibody-producing cells in the case of patients with SLE. Numerous deficiencies in T cell function were described, including

altered production of typical T cell cytokines, such as interleukin (IL)-2, and studies of murine lupus models strongly supported the essential role that T cells play in lupus pathogenesis.

The discovery of Toll-like receptors (TLR) in the 1990s, the recognition that those receptors recognize common determinants expressed by microbes, and the demonstration that TLRs mediate immune system activation was a major advance and perhaps the most significant milestone in many decades. These findings have led to gains in understanding of lupus pathogenesis. Characterization of the typical exogenous ligands of each of the TLRs has been followed by identification of endogenous ligands for their receptors. Nucleic acids are the most relevant for amplification of immune system activation and autoimmunity in SLE. It is not yet clear whether the TLRs act to augment immunologic activity that is initiated by other molecular pathways or if they are also essential as sensors for the primary initiators of autoimmune disease.

In spite of these considerable gains in elucidating the pathogenesis of SLE, the environmental triggers and genetic susceptibility factors that lead to the initiation of autoimmunity in some individuals but not others remain largely undefined. Regarding triggers of disease, clinical observations have pointed to exposure to sunlight, microbial infection, and certain drugs as factors that can lead to initiation or exacerbation of lupus. Whether there is a common thread among these environmental triggers is not clear, but ultraviolet (UV) light–mediated DNA damage and modification of DNA methylation are among the processes that might render self-nucleic acid stimulatory to the immune system. Oxidative damage to cell proteins could alter cell function and impair immune system regulation.

Significant technologic advances in recent years, together with development of consortia of investigators who have cooperated to share biologic samples from patient cohorts and control participants, have supported important progress in defining the genetic variants that show a statistical association with a diagnosis of SLE. These recent genome-wide association studies (GWAS) have used the long-standing observations of the high risk of disease in patients with complement deficiencies to help identify lupus-associated genes that encode important components of molecular pathways that promote production of type I interferon (IFN), alter the threshold for activation of lymphocytes, or generate immune stimuli. In addition, new concepts suggested by single-gene mutations that alter regulation of genome integrity and nucleic acid degradation, resulting in lupus-like clinical syndromes, point to the significance of endogenous nucleic acids as candidate disease triggers.[1,2]

Together, these scientific advances have led to the recent, long-awaited activity in drug development programs that target mechanisms likely to affect lupus disease activity or clinical progression. This chapter reviews recent studies that have illuminated the immunopathogenesis of SLE.

## GENETIC CONTRIBUTIONS TO LUPUS PATHOGENESIS

Current concepts in genetic studies of complex human diseases, including SLE, identify common variants with a small impact on risk of disease, as well as low-frequency mutations that can have a great impact on the risk for lupus or a lupus-like syndrome.

Observations of the occurrence of several individuals with SLE within a family, along with a high frequency of concordance of SLE in identical twins, have pointed to a strong genetic contribution to SLE. Data suggest that concordance of clinical lupus disease in twins is 10 times more frequent in monozygotic than in dizygotic twins, although the highest reported concordance rate is still only 57%. Moreover, the suggestion that multiple autoimmune diseases are associated with common genetic susceptibility factors is supported by the aggregation of several distinct autoimmune diseases within a family. The pace of discovery of common genetic variants, typically identified by statistical analysis of single nucleotide polymorphisms (SNPs) in relation to a diagnosis of SLE, has markedly accelerated in recent years because the cost of genotyping thousands of patient and control samples has made studies feasible. Publication of eight collaborative GWAS, along with meta-analyses, have identified more than 50 genes or genomic loci associated with SLE.[3] A common theme among many of the lupus-associated genes is that they encode proteins implicated in immune system function. Although this result is not surprising, it confirms the essential contribution of the immune system to the autoimmunity, inflammation, and tissue damage that characterize lupus disease and points to the most significant molecular pathways that mediate altered immune function. Additional disease-associated sequence variants and studies defining DNA hypersensitive sites, potentially reflecting chromatin that is accessible to DNA-binding proteins, have been identified through the Encyclopedia of DNA Elements (ENCODE) consortium and suggest a role for regulatory elements that orchestrate complex gene expression programs relevant to lupus pathogenesis.[4]

The lupus-associated genes that contribute to lupus pathogenesis can be considered in relation to their roles in immune function (Tables 79-1 and 79-2). In parallel to the requirements for immune system activation stimulated by foreign antigens, SLE-associated genes are involved in generation of self-antigen, activation of the innate immune response, and activation of the adaptive immune response.

**TABLE 79-1** Genetic Variants Associated with Systemic Lupus Erythematosus—Major Histocompatibility Complex Genes

| **Major Histocompatibility Complex Genes Associated with SLE** |
|---|
| Homozygous deficiencies of early complement components (C2, C4A, C4B) (increase risk 5- to 10-fold) |
| *HLA-DR2* (increases relative risk twofold to threefold) |
| *HLA-DR3* (increases relative risk twofold to threefold) |
| *DR2/DRX* associated with anti-Sm antibodies |
| *DR3/DRX* associated with anti-Ro and anti-La antibodies |
| *DR2/DR3* associated with anti-Ro, anti-La, and/or anti-Sm and also associated with anti-dsDNA antibodies |
| *DR3/DR3* associated with anti-Sm antibodies |

**TABLE 79-2** Genetic Variants Associated with SLE—Non-MHC Genes

| Non-MHC Genes Associated with SLE |
|---|
| Homozygous deficiency of C1q (increases risk 5- to 10-fold) |
| **Associations Based on Linkage Studies** |
| Fc gamma receptor IIa *(FCGR2A)* |
| Fc gamma receptor IIIa *(FCGR3A)* |
| Fc gamma receptor IIb *(FCGR2B)* |
| Programmed cell death 1 *(PDCD1)* |
| **Associations Based on Candidate Gene Studies** |
| C-reactive protein *(CRP)* |
| Interleukin-10 *(IL-10)* |
| Interferon regulatory factor 5 *(IRF5)* (supported by GWAS) |
| Protein tyrosine phosphatase 22 *(PTPN22)* (supported by GWAS) |
| **Associations Based on or Confirmed by Genome-Wide Association Studies** |
| AF4/FMR2 family, member 1 *(AFF1)* |
| AT-rich interactive domain 5B *(ARID5B)* |
| Autophagy-related 5 *(ATG5)* |
| B cell scaffold protein with ankyrin repeats *(BANK1)* |
| B lymphocyte-specific tyrosine kinase *(BLK)* |
| *CD80* |
| Cyclin-dependent kinase inhibitor 1B *(CDKN1B)* |
| C-type lectin domain family 16, member A *(CLEC16A)* |
| C-Src tyrosine kinase *(CSK)* |
| DNA-damage regulated autophagy modulator *(DRAM1)* |
| E74-like factor 1 *(ELF1)* |
| V-ETS avian erythroblastosis virus E26 oncogene homolog 1 *(ETS1)* |
| Intercellular adhesion molecule 1/4/5 *(ICAM1/4/5)* |
| Interferon induced with helicase C domain 1 *(IFIH1/MDA5)* |
| IKAROS family zinc finger 1 *(IKZF1)* |
| IKAROS family zinc finger 3 *(IKZF3)* |
| Interleukin-21 *(IL-21)* |
| IL-1 receptor-associated kinase/methyl-CpG-binding protein 2 *(IRAK1/MECP2)* |
| Interferon regulatory factor 7 *(IRF7)* |
| Interferon regulatory factor 8 *(IRF8)* |
| Integrin alpha M *(ITGAM)* |
| JAZF zinc finger 1 *(JAZF1)* |
| V-yes-1 Yamaguchi sarcoma viral–related oncogene homolog *(LYN)* |
| *MIR146A* |
| Neutrophil cytosolic factor 2 *(NCF2)* |
| Nicotinamide nucleotide adenylyltransferase 2 *(NMNAT2)* |
| Pyruvate dehydrogenase complex, component X/CD44 *(PDHX/CD44)* |
| PHD and ring finger domains 1 *(PHRF1)* |
| PR domain-containing 1, with ZNF Domain (BLIMP1) *(PRDM1)* |
| Protein kinase C, beta *(PRKCB)* |
| Pituitary tumor-transforming 1 *(PTTG1)* |
| PX domain-containing serine/threonine kinase *(PXK)* |
| RAS guanyl-releasing protein 3 *(RASGRP3)* |
| Solute carrier family 15, member 4 *(SLC15A4)* |
| Signal transducer and activator of transcription 4 *(STAT4)* |
| Tet methylcytokine deoxygenase 3 *(TET3)* |
| Toll-like receptor 7 *(TLR7)* |
| Transmembrane protein 39A *(TMEM39A)* |
| Tumor necrosis factor-α–induced protein 3 *(TNFAIP3)* |
| TNFAIP3-interacting protein 1 *(TNIP1)* |
| Tumor necrosis factor superfamily, member 4 *(TNFSF4/OX40L)* |
| Three-prime repair exonuclease 1 *(TREX1)* |
| Tyrosine kinase 2 *(TYK2)* |
| Ubiquitin-conjugating enzyme E2L 3 *(UBE2L3)* |
| UHRF1-binding protein 1 *(UHRF1BP1)* |
| WDFY family member 4 *(WDFY4)* |
| XK, Kell blood group complex subunit–related family, member 6 *(XKR6)* |
| **Rare Genetic Mutations Associated with Lupus** |
| Three-prime repair exonuclease 1 *(TREX1)* |
| Ribonuclease H2, subunit A-C *(RNASEH2A-C)* |
| SAM domain and HD domain 1 *(SAMHD1)* |
| Adenosine deaminase, RNA-specific *(ADAR)* |

AT, Adenine, thymine; ETS, E26 transformation-specific; GWAS, genome-wide association study; MHC, Major Histocompatibility Complex; PHD, plant homeodomain; PR, positive regulatory; SAM, *S*-adenosylmethionine; SLE, systemic lupus erythematosus.

Although in most cases the specific functional alterations that are conferred by the lupus-associated variant compared with the more common variant have yet to be defined in detail, sufficient information exists regarding its function for hypotheses to be developed and tested in functional genetic studies.

The rare but high-risk deficiencies in complement pathway gene products, including C2, C4, and C1q, are thought to contribute to lupus pathogenesis by impairing clearance of cellular debris, a function that is typically supported by those complement components. Increased availability of nuclear debris can provide sufficient self-antigen for induction of self-reactive T cells, or serve as an endogenous adjuvant for activation of the innate immune response. The ancestral major histocompatibility complex (MHC) 8.1 haplotype block, human leukocyte antigen (HLA)-B8/DR3/DQw2/C4AQO, that is associated with lupus susceptibility, encodes the alleles B8 and DR3 and bears a short *C4B* gene and no *C4A* gene, whereas other nonrisk haplotypes carry either a longer *C4B* segment and/or one or more copies of *C4A*. In fact, the relative risk related to the *C4A* null allele is twice that of either HLA-B8 or DR3, pointing to the significance of the C4 genes in disease risk.[5] It should be noted that this risk haplotype is also associated with accelerated disease in patients infected with human immunodeficiency virus (HIV), insulin-dependent diabetes mellitus, and several other autoimmune diseases. Deficiency of C1q, the recognition protein for the classical complement pathway, might contribute to disease on the basis of its important role in promoting clearance of apoptotic cell debris by mononuclear phagocytes.[6] C1q plays an additional role in inhibition of IFN-α production by directing stimulatory immune complexes to monocytes rather than IFN-producing plasmacytoid dendritic cells (pDCs). Through this mechanism C1q deficiency can augment IFN-α and promote broad immune dysregulation.[7] C-reactive protein (CRP), a member of the pentraxin family, also contributes to clearance of apoptotic debris. Polymorphisms in *CRP* have been associated with SLE and with decreased levels of CRP, but it remains unclear how much of the genetic contribution to basal CRP levels is caused by variations within the gene itself versus variations in other genes.

Recent studies of families with a lupus-like disease, the Aicardi-Goutières syndrome (AGS), suggest that mutations in genes that regulate the integrity of endogenous DNA or RNA might result in excess stimulatory nucleic acid and innate immune system activation.[8-11] AGS is characterized by skin lesions, autoantibodies, central nervous system disease, and high levels of type I IFN, but unlike SLE it is typically diagnosed in young children. Mutations in the *TREX1* gene, encoding a DNase that is required to degrade potentially stimulatory reverse-transcribed DNA, were identified in patients with AGS, and a functional connection between *TREX1* and control of type I IFN production was demonstrated in a murine model in which *TREX1* deficiency resulted in increased levels of IFN-β.[12] A recent analysis of more than 8000 lupus patients found *TREX1* mutations in approximately 0.5% of patients. In addition, a common variant in the *TREX1* gene conferred an odds ratio for diagnosis of lupus of 1.73 compared with healthy controls.[13] Mutations in *SAMHD1*, encoding an enzyme that

removes phosphates from deoxyribonucleotide triphosphate (dNTPs), reducing available nucleotides for reverse transcription, have also been identified in AGS patients and are associated with triggering of a DNA damage response and type I IFN production.[10] Mutations in members of the *RNASEH2* family that remove ribonucleotides from RNA-DNA hybrids also activate an innate immune response and are associated with a diagnosis of AGS.

A recent study of parents of AGS patients with *RNASEH2* mutations implicated that gene in protection from autoimmunity. Parents who were heterozygous for the variant *RNASEH2* demonstrated an intermediate autoimmune phenotype characterized by anti-nuclear antibodies, and showed accumulation of ribonucleotides in their genomes, generation of DNA damage characterized by elevated cyclobutane pyrimidine dimer formation, and activation of the p53 pathway.[14] *ADAR*, with mutations also reported in association with AGS, encodes an RNA-specific adenosine deaminase that converts adenosine to inosine in dsRNAs, particularly those enriched in Alu sequences, and typically functions as a suppressor of the cell intrinsic type I IFN response.[11] Each of these gene products plays a role in control of the quality of endogenous nucleic acids, reduces the risk to the genome of production of endogenous virus-like transposons, and appears to be important for avoiding aberrant activation of an innate immune response characterized by IFN pathway activation. Collectively, these syndromes have been termed *interferonopathies* and provide important clues to pathogenic mechanisms relevant to SLE.[11]

A syndrome with some features consistent with the vasculopathy that characterizes many patients with SLE or systemic sclerosis develops in young children with mutations in *TMEM173*, encoding STING (stimulator of interferon genes), a cytosolic DNA sensor and an essential component of the TLR-independent pathway of immune system activation.[15] Skin rash, a livedo-like vascular pattern, distal extremity ulcerations, interstitial lung disease, markers of systemic inflammation, and low-titer autoantibodies are among the clinical characteristics of patients with *STING* gain-of-function genetic alterations. These patients show increased transcription of IFN-β and IFN-stimulated genes and constitutive phosphorylation of signal transducer and activator of transcription (STAT)1, a signaling component of the Janus kinase (JAK)-STAT pathway that is activated downstream of IFNAR, the type I IFN receptor. In vitro studies that use a JAK inhibitor support targeting the effector arm of the IFN pathway in this syndrome.[15] Taken together, these recent demonstrations of the association of rare genetic variants of enzymes that regulate degradation of nucleic acids with SLE or lupus-like syndromes point to the central role of those nucleic acids as triggers for immune system activation and disease.

In addition to the information provided by the rare mutations described previously, a large number of lupus-associated SNPs found in genes that encode proteins involved in induction of type I IFN or response to that family of cytokines draw additional attention to the important role of type I IFN and the innate immune response in SLE pathogenesis.[16-18] IFN regulatory factor 5 (IRF5) and IRF7 are cytoplasmic proteins that translocate to the nucleus after effective activation of the endosomal TLRs by DNA or RNA. IRF5 and IRF7 then act as transcription factors to initiate transcription of IFN-α and other pro-inflammatory mediators. *TNFAIP3* encodes A20, a protein that regulates several pro-inflammatory cellular mechanisms, including signaling through endosomal TLRs and activation of nuclear factor-κB (NF-κB).[19] Genetic variants in *IRF5*, *IRF7*, *TNFAIP3*, *TNIP1*, and numerous other lupus-associated genetic variants can be mapped to molecular pathways responsible for induction of innate immune system activation or responsiveness to its products, particularly IFN-α.[3]

A third set of lupus-associated gene variants contributes to altered thresholds for lymphocyte activation or efficiency of cell signaling. The ancestral MHC 8.1 haplotype that is strongly associated with a diagnosis of SLE, along with other autoimmune diseases, appears to influence the early stages of immune system activation. Although more efficient presentation of self-antigens by disease-associated class II MHC alleles would seem to be the most likely mechanism by which the MHC risk haplotype confers predisposition to autoimmunity, the available data point to a number of immune alterations, many focused on the T cell, in healthy individuals who carry the ancestral haplotype.[5] The impact of those alleles is best defined clinically as determining immune responses that generate particular autoantibody specificities, and the alleles seem to be important in determining whether anti-DNA autoantibodies, antibodies specific for RNA-associated proteins, or both. can be induced and produced through T cell–dependent B cell differentiation.[20] Additional lupus-associated variants that alter adaptive immune system activation are involved in cytokine signaling, such as *STAT4*, or efficiency of signaling downstream of the T and B cell surface antigen receptors, such as *PTPN22* in the case of both T and B cells, and *LYN*, *BANK*, *BLK*, *TNFAIP3*, and others in the case of B cells.[3] MicroRNAs are RNA transcripts that regulate longevity of target mRNAs and represent another source of genetic variability that can impact adaptive immune system regulation.[21]

A fourth category of lupus-associated genetic variants defines determinants of target organ damage. The understanding of genetic determinants of target organ vulnerability to immune-mediated or oxidative damage is less well developed than the role of genetic variants in altered immune system function in SLE. In addition to SNPs in *TNIP1*, encoding a protein associated with TLR signaling and risk of lupus nephritis, recent studies have found an association between *MTMR3*, which encodes myotubularin-related protein 3, with lupus nephritis, and a link between alleles of *APOL1*, involved in cholesterol transport, and end-stage renal disease. The link in the latter disease occurs particularly in African Americans.[22-25] Table 79-1 and 79-2 list many of the genetic variants documented to have a statistical association with a diagnosis of SLE.

Although impressive progress based on GWAS has identified statistical association of sequence variations in genes or genetic loci with a diagnosis of SLE, the functional consequences of those variations have not been extensively characterized. The best developed insights regarding the impact of lupus-associated variants on immune function have derived from studies of gene products involved in production of type I IFN. The risk alleles for *IRF5* and *IRF7* are associated with increased serum type I IFN activity in

those patients who demonstrate autoantibodies targeting DNA or RNA-associated proteins.[16,26] Those studies support the hypothesis that nucleic acid–containing immune complexes are important stimuli that act through endosomal TLRs such as TLR7 and TLR9, those TLRs that mediate cell signals through the IRF5 and IRF7 transcription factors.[1,2]

The impressive collaborative efforts that have successfully collected sufficient patient and control samples and performed the required genotyping and statistical analyses have defined or at least confirmed those molecular pathways that are central to the immunopathogenesis of SLE. The strong support for activation and altered regulation of the TLR pathway, along with variations in lymphocyte signaling, point to potential therapeutic targets for future study. In addition, the recent identification of rare mutations in enzymes required for degradation or regulation of intracellular nucleic acids suggests that further study of the TLR-independent pathways of innate immune system activation, mediated by nucleic acid sensors and their associated kinases and adaptor molecules as well as DNA damage pathways might be fruitful areas for further investigation.

Subphenotype analysis will continue to amplify the information that can be gleaned from patient and control genotyping. A study of anti-dsDNA$^+$ and anti-dsDNA$^-$ SLE patients, along with healthy controls, identified HLA-DR3, *STAT4*, and *ITGAM* as significantly associated with the presence of anti-dsDNA antibodies.[27] A case-only analysis additionally associated *PTPN22*, *IRF5*, and *PTTG1* with anti-dsDNA antibodies. In contrast, a distinct group of lupus-associated genes showed comparable association between anti-dsDNA positive and negative patients, including *FCGR2A*, *OX40L*, *IL10*, *PXK*, *UHRF1BP1*, *PRDM1*, *BLK*, and *IRAK1*. Although it is possible that some of these variants are associated with distinct autoantibody specificities, it is more likely that they represent risks for general immune system activation, inflammation or tissue damage.

Whether the insights regarding specific genetic susceptibility factors can be used to predict development of lupus or particular manifestations of disease is as yet unclear. Recent studies have attempted to determine the predictive value of accumulated genetic risk variants. Although increased numbers of lupus-associated alleles are associated with some increased risk of disease and the number of lupus-associated genetic alleles is significantly higher in patients with anti-dsDNA antibodies than in those without those autoantibodies, at this time, it would not appear that genotyping for lupus risk is sufficiently informative to warrant practical application in patient management.[28]

## FEMALE PREDOMINANCE OF SYSTEMIC LUPUS ERYTHEMATOSUS

A discussion of genetic contributions to SLE pathogenesis cannot ignore the dramatic 9:1 female predominance of the disease. Of all of the characteristic clinical features of lupus, it is the extreme sex skewing that remains least understood. Hormonal contributions to immune system activation are likely to represent a component of the female predominance of the disease; estrogen can modulate lymphocyte and pDC activation, and prolactin is expressed at increased levels in lupus serum.[29]

Even given the contribution of hormones to increased immune activation, additional factors should be examined to understand why 9 or 10 females are diagnosed with SLE for every male lupus patient. It is intriguing that Klinefelter's syndrome, characterized by a 47,XXY genotype, is increased 14-fold among men with SLE compared with men without SLE.[30] These data are proposed to suggest an X chromosome gene dose effect as an important contributor to SLE pathogenesis. Identifying the X chromosome as a possible risk factor for SLE provides a basis for new hypotheses regarding disease susceptibility, but the nature of that risk remains undefined. A possible role for altered regulation of epigenetic processes, such as DNA methylation, has been raised, and murine studies have supported the impact of duplications of portions of the X chromosome that encode the *TLR7* gene in activation of the innate immune system, production of type I IFN, and generation of autoimmunity.[31] Of note, recent data that used a humanized mouse model support roles for both estrogen and X chromosome dosage in augmented pDC production of type I IFN in response to TLR7 ligation.[32] Investigation of altered gene dosage in human patients has not confirmed a duplication of the *TLR7* gene, and studies of DNA methylation are most suggestive of altered DNA methylation reflecting generalized immune activation, with a particular focus on type I IFN–stimulated genes, rather than a primary etiologic event.[33] However, the *TLR7* gene is located on a region of the X chromosome in which escape from X chromosome inactivation has been documented, so further studies of epigenetic regulation of X chromosome structure and gene expression are warranted.[34]

A potential pathogenic role for the distinct events that occur in the ovary compared with those in the testes also deserves further study. The onset of SLE most typically occurs in the childbearing years, after menarche and before menopause. A positive association between early menarche and SLE has been observed, and breastfeeding confers a protective effect.[35] Both observations might be consistent with molecular and cellular events related to ovulation as factors contributing to lupus pathogenesis. It is intriguing to consider that the biology of germ cell maturation, with female germ cells undergoing a second meiotic division before ovulation each month, might involve mechanisms and mediators that affect immune recognition. Although not yet fully understood, the carefully orchestrated demethylation and remethylation of DNA, along with the production of regulatory RNAs and RNA-associated proteins such as so-called PIWI proteins, in the germ cells and associated somatic cells might provide a source of stimulatory nucleic acid–containing complexes that could access TLR-dependent or TLR-independent pathways and result in immune activation.[36] The challenge in pursuing such concepts is the obvious limitation on access to ovarian tissue for study, although murine models might be helpful in that regard.

## ENVIRONMENTAL TRIGGERS OF LUPUS

Concordance rates for development of SLE in identical twins range from 24% to 57%, indicating that that both environmental factors and stochastic events (i.e., chance) contribute to development of SLE in an individual.

*Although each drug listed and many others can induce lupus-like symptoms in predisposed individuals, there is little evidence that they can induce true SLE or even activate disease in individuals with spontaneous, established SLE. If the clinical care of a patient with SLE would benefit from the use of one of these drugs, the drug should not be withheld.

SLE, Systemic lupus erythematosus.

Although some environmental triggers of disease have been identified on the basis of clinical observation and epidemiologic studies (Table 79-3), in general there is incomplete understanding of the range of factors that can induce disease and the mechanisms by which they do so.[37] Socioeconomic factors have been demonstrated to contribute to poor outcomes in lupus patients, likely related to poor access to care.[38] The distinct contributions of low socioeconomic status versus genetic factors that impact disease severity in certain ethnic groups are difficult to dissect.

Clinical manifestations that are often present at the time of diagnosis, including fatigue and arthralgias, have suggested that a virus might initiate the disease. In fact, epidemiologic studies demonstrating higher prevalence of antibodies specific for Epstein-Barr virus (EBV) antigen in children with SLE compared with the general population, as well as higher frequency of anti-EBV antibodies in a military cohort before diagnosis of lupus, support a possible role for that virus in disease pathogenesis.[39] In addition, SLE patients demonstrate increased EBV DNA in blood.

Several potential mechanisms might account for a pathogenic role for EBV in SLE, including production of EBV-encoded RNAs that induce type I IFN, utilization of B cell signaling pathways to promote B cell activation and differentiation, and generation of autoantibodies reactive with DNA- or RNA-binding proteins through a molecular mimicry mechanism.[40] EBV-encoded small RNAs, or EBERs, are expressed in cells latently infected with EBV. EBERs induce expression of type I IFN after binding to the dsRNA-dependent protein kinase (PKR) and activating signaling through a TLR-independent pathway. Latent membrane protein 1, encoded by EBV, can act as a mimic of CD40 and promote B cell dysfunction and autoimmunity in lupus-susceptible mice.[41] A recent study demonstrates that antibodies specific for the virus-encoded EBNA-1 protein can also react with dsDNA.[42] The molecular basis of this apparent cross-reactivity is not known, although DNA can associate with EBNA-1 and might account for the described antibody reactivity. T cell responses specific for EBV have been studied in patients with lupus and found to be deficient, perhaps contributing to the increased numbers of EBV-infected mononuclear cells and increased copy number of EBV DNA found in SLE patients.[43]

Although EBV may or may not be an important etiologic agent in SLE, recent studies of murine models of persistent infection with lymphocytic choriomeningitis virus provide a useful system for study of pathogenic mechanisms that appear highly relevant to the immunopathogenesis of SLE.[44-46] Sustained production of type I IFN and a shift from expansion of T effector cells to expansion of T follicular helper cells accompanies the organ inflammation and damage that characterize those models of persistent virus infection. In the mice with prolonged production of IFN, blockade of the type I IFN receptor abrogates tissue damage. Data from comparisons of immune system function in patients with HIV-1 infection to macaques with infection with the related but less lethal simian version of the virus further support a view of chronic production of type I IFN as an important mechanism that promotes widespread inflammation similar to that seen in patients with lupus.[47] These models of chronic viral infection provide a guide for further study of key mechanisms that sustain disease in patients with lupus, and the growing interest in the impact of the microbiome on immune function will likely generate additional new hypotheses.

Environmental toxins are of interest, yet their potential role in lupus pathogenesis has not been comprehensively explored. Data support current smoking as a risk factor for SLE, with a dose response relating pack years of smoking to risk. As is currently proposed with regard to pathogenesis of rheumatoid arthritis, smoking might provide an inflammatory stimulus to epithelial or mononuclear cells in the lungs, promoting protein modification or nonspecific inflammation. Silica has also been proposed as a potential pathogenic factor in SLE on the basis of its known capacity to serve as an adjuvant.[48]

Two well-described triggers of lupus, ultraviolet light and certain drugs, are likely to promote lupus pathogenesis through their effects on DNA. UV light has many effects on skin cells, including induction of DNA breaks that might alter gene expression or lead to apoptotic or necrotic cell death. Even in the absence of cell death, DNA breaks or prolonged maintenance of DNA-protein cross-links might provide either an adjuvant or antigenic stimulus to the immune system. In that regard, recent data show UV-induced generation of cyclobutane pyrimidine dimers and induction of IFN-stimulated genes in cells from individuals heterozygous for mutations in *RNASEH2* genes, encoding enzymes that remove ribonucleotides from genomic DNA.[14] Altered DNA methylation has been proposed as a likely mechanism

of drug-induced lupus.[49] In the case of hydralazine, the drug inhibits extra-cellular signal-regulated kinase (ERK) pathway signaling, resulting in decreased expression of DNA methyltransferase (DNMT) 1 and DNMT3a, two enzymes that mediate DNA methylation.[50] Modification of ERK signaling can be mediated by the effects of oxidizing agents on protein kinase C delta, an upstream regulator of ERK.[51] Altered DNA methylation modifies gene expression and might also expose potential ligands for nucleic acid sensors, promoting immune system activation.

## INNATE IMMUNE SYSTEM ACTIVATION IN SYSTEMIC LUPUS ERYTHEMATOSUS

Arguably the most significant recent advance that has improved understanding of the pathogenesis of SLE and other autoimmune and inflammatory diseases is the discovery of the TLRs and, more generally, the elucidation of the central role of innate immune system activation in regulation of the adaptive immune response, inflammation, and tissue repair.[52] The TLRs are composed of an ectodomain with leucine-rich repeats, a transmembrane domain, and a cytoplasmic domain that associates with adaptor molecules that initiate signaling, resulting in activation of members of the IFN-regulatory factor family, NF-κB, and members of the mitogen-activated protein (MAP) kinase family. TLR-independent innate immune activation can be initiated by intracytoplasmic RNA sensors, such as RIG-I and MDA5, that signal through a mitochondrial adaptor protein, MAVS, to activate IKK-ε and TBK1.[53,54] DNA sensors include IFI16, DAI, and the nucleotidyltransferase cGAS, which generates a 2′-5′ linked cyclic dinucleotide, cGAMP, that binds the endoplasmic reticulum protein STING, also resulting in activation of TBK1.[55-57] Recognition of both RNA and DNA leads to activation of IRF3 as well as NF-κB, which serve as transcription factors that generate IFN-β and other pro-inflammatory mediators.[58] Although these nucleic acid sensing pathways likely evolved to detect infectious viruses, they can also be triggered by endogenous nucleic acids. During the past decade, studies of nucleic acid–responsive TLRs and TLR-independent nucleic acid sensors that result in production of type I IFNs and other pro-inflammatory mediators have identified a direct pathogenic role for nucleic acids and nucleic acid–containing immune complexes as mediators of immune dysfunction in lupus. These studies complement the demonstration of broad expression of type I IFN–inducible genes in peripheral blood cells of lupus patients, referred to as the "IFN signature."[59-61] Together, the data point to the innate immune response and its products as significant factors in lupus pathogenesis. Table 79-4 describes many of the key components of the TLR-dependent and TLR-independent immune system pathways that are important in activation and control of lupus immune responses.

The endosomal TLRs, particularly TLR7, reactive with single-stranded RNA, and TLR9, reactive with unmethylated CpG-rich DNA, have been associated with lupus pathogenesis on the basis of in vitro studies that demonstrate activation of those TLRs by immune complexes that gain access to their intracytoplasmic compartment with the help of Fc receptors that bind the Fc fragment of immunoglobulin in the complex.[62-64] Clinical data demonstrating association of autoantibodies with specificity for RNA-binding proteins (such as Ro, La, Sm, and RNP) with high expression of IFN-induced genes in patient peripheral blood cells point to a significant role for RNA-containing immune complexes in innate immune activation and IFN production.[65] Associated neutrophil-derived proteins, including

SLE, Systemic lupus erythematosus; TLR, Toll-like receptor.

high mobility group box 1 (HMGB1) and the cathelicidin protein LL37, can facilitate access of those immune complexes to the TLR-containing endosome.[66] Lupus mice made deficient in one or another TLR have supported the role of TLR7 in generating type I IFN, autoantibodies specific for RNA-binding proteins, and disease.[67] TLR9 activation can also generate IFN-α, but the findings from *TLR9*-deficient MRL/*lpr* (Fas-deficient) mice have been somewhat confusing because those mice show more severe disease, suggesting that the activation of TLR9 might actually be protective. It appears that TLR9 activation can regulate the *TLR7* pathway, resulting in reduced production of RNA-related autoantibodies.[68] In addition to demonstrating the important role of the endosomal TLRs in lupus pathogenesis, the data link TLR pathway activation with production of particular autoantibody specificities. These significant advances in characterization of the role of TLRs and the innate immune response in lupus disease have suggested new therapeutic targets that are currently under consideration (Figure 79-2).

The elucidation of the mechanisms of induction of type I IFN, with pDCs the major producers, have promoted studies that identified roles for additional cell types in amplification of this pathway. Platelets, largely ignored in studies of SLE pathogenesis, were shown to promote IFN production by pDCs through signals mediated by CD40 ligand (CD154) on activated platelets and CD40 on the pDCs.[69] One of the initial microarray data sets demonstrating an IFN gene expression signature in peripheral blood cells of pediatric lupus patients also detected expression of genes that are typically expressed in granulocytes.[59] Recent studies from several groups have extended this observation

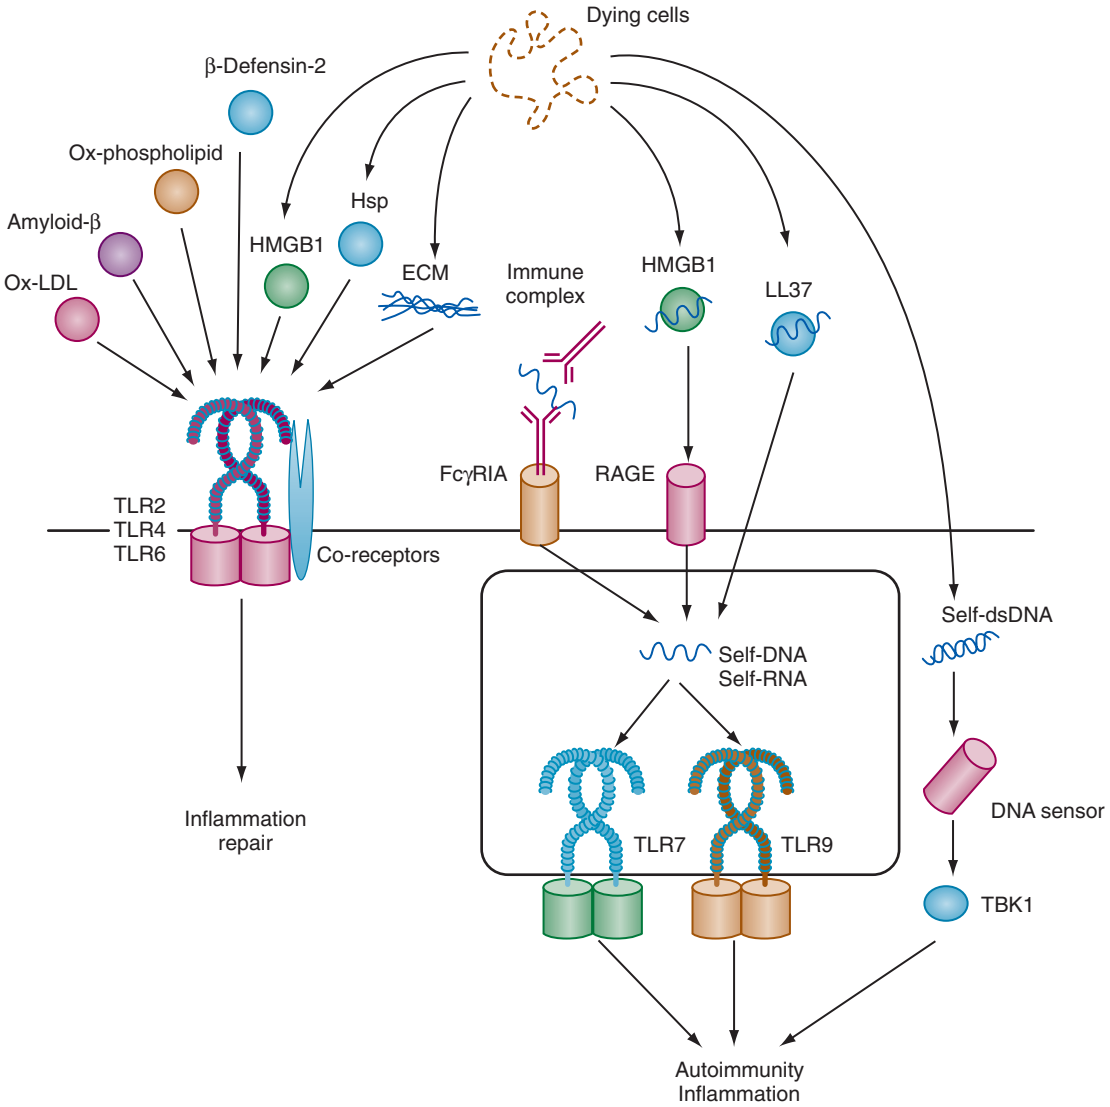

**Figure 79-2** Endogenous stimuli for innate immune system activation. Endogenous molecules released by dying cells, such as high-mobility group box 1 (HMGB1) and β-defensins, are recognized by cell surface Toll-like receptors (TLRs) and induce production of inflammatory mediators. Self-DNA or self-RNA either in association with HMGB1 or LL37 or in the form of immune complexes that bind Fc receptors, is internalized into endosomal TLRs and transducer signals that result in transcription of type I interferon or pro-inflammatory cytokines. Self-nucleic acids can also be recognized by cytoplasmic sensors and trigger gene expression that contributes to immune activation, autoimmunity, and inflammation. and have documented low-density granulocytes in the circulation of lupus patients.[70]

Neutrophil extra-cellular traps (NETs) have gained attention as potential mediators of innate immune system activation. The NETs derive from a discrete cellular process, termed *NETosis*, in which aggregates of nuclear or mitochondria-derived DNA and its associated histones, HMGB1, LL37, elastase, and myeloperoxidase are systematically extruded into the extra-cellular environment. Generation of the NETs can be induced by interaction of neutrophils with vascular endothelial cells, activated platelets, or various cytokines. Recent data also implicate nucleosomes and RNA-containing immune complexes in the induction of NETosis.[71-73] Although NETs have only recently been linked to SLE, they present an intriguing and possibly significant mechanism that might account for observed alterations in immune function. They have the capacity to induce production of type I IFN by pDCs, serve as a source of relevant self-antigens for presentation to T lymphocytes, and mediate vascular damage and thrombosis.[74]

As described earlier, the elucidation of a significant role for the nucleic acid–sensing TLRs in recent years has drawn attention to the important role of autoantigen in driving disease in lupus. The contribution of apoptotic debris, either through increased apoptosis and/or impaired clearance of apoptotic cells, has been assumed for a number of years to be at least one likely mechanism that drives immune system activation and focuses its specificity on nucleic acids and their associated proteins. Apoptotic blebs are enriched in the typical targets of autoantibodies, such as Ro and Sm. Recent attention on so-called *microparticles*, small membrane-enclosed particles released by activated and dying cells, has generated data demonstrating binding of those particles by some autoantibodies in lupus plasma.[75] A combination of increased generation of nuclear material, perhaps modified by oxidative stress, and impaired clearance may be important mechanisms of lupus immunopathogenesis.[76] The role of C1q and complement components in the clearance of apoptotic debris has been suggested as an explanation for the strong association of C1q, C2, and C4 deficiencies with SLE.[77] A second role for complement components that likely reduces the pathogenicity of immune complexes is the capacity of complement to solubilize immune complexes, reducing the likelihood that those complexes would deposit in tissue and cause damage.[78]

## ADAPTIVE IMMUNE SYSTEM ALTERATIONS IN SYSTEMIC LUPUS ERYTHEMATOSUS

T cell function has been carefully studied in SLE patients for several decades, and deficiencies or alterations in signaling pathways, production of cytokines, cell proliferation, and regulatory functions have been documented.[79] $CD4^+$ T cells are viewed as a requirement for development of lupus on the basis of their essential role in providing helper signals that drive differentiation of B cells to autoantibody-producing cells. Although some in vitro experiments support the capacity of cytokines such as IL-21 and B cell–activating factor (BAFF)/B lymphocyte stimulator (BLyS) and TLR ligands to mediate antibody production by B cells, T cells are recognized as the most efficient drivers of B cell differentiation.[80]

The activation status and signaling mechanisms of lupus T cells are distinct from those of T cells from healthy individuals. Among the alterations in function is decreased proliferation in response to self–non–T cells or allogeneic–non–T cells or in response to presentation of soluble antigens. In contrast, T cell proliferation induced by direct activation of the T cell antigen receptor is at least as strong as observed in control cells. Lupus T cells readily express CD40 ligand (CD154) after activation and maintain expression of that important co-stimulatory molecule longer than control T cells, leading to augmented help for activation and differentiation of B cells exposed to those T cells. Another long-standing observation is that lupus T cells produce less IL-2 than control T cells, perhaps one factor that contributes to impaired generation of IL-2–dependent T regulatory cells. The molecular basis of the altered T cell activation in lupus patients is complex, but at least one factor might be the observed substitution of the T cell receptor zeta chain with the common gamma chain that is a component of the Fc receptor signaling machinery. Correction of this defect can normalize T cell signaling and IL-2 production.[81] Augmented calcium responses following T cell receptor ligation have been observed, and hyperpolarization of mitochondria in T cells has been associated with altered T cell activation and function.[82]

An interesting observation from studies of lupus T cells might reflect more global epigenetic alterations to the lupus genome that impact autoimmunity. Treatment of mouse and human T cells with 5-azacytidine resulted in increased expression of the lymphocyte function antigen-1 (LFA1; CD11a) adhesion molecule and increased proliferative responses to self–non–T cells.[83] Lupus T cells studied ex vivo show hypomethylation of CG-rich areas of the genome, and a recent report of genome methylation in identical twins discordant for lupus demonstrated relatively less methylation of the twin with active lupus.[84] Multiple mechanisms have been postulated to contribute to DNA demethylation in lupus lymphocytes, including increased expression of growth arrest and DNA damage–induced 45alpha (GADD45alpha), a protein that removes methyl groups from DNA, decreased expression of DNMT1, and altered ERK pathway signaling.[50]

Generalized lymphopenia is typical of SLE, but expansions of specific T cell populations have been described. The T follicular helper population, characterized by expression of ICOS, CXCR5, and Bcl-6 and by production of IL-21, mediates important signals that promote differentiation of autoantigen-specific B cells.[85,86] A population of $CD8^+$ cells with a memory phenotype is associated with poor prognosis, possibly based on tissue damage mediated by those cells.[87]

The regulation and function of T regulatory cells (Tregs), with capacity to suppress immune responses, and Th17 cells, which promote inflammation by production of IL-17, have been intensively studied in recent years. Some studies of lupus patients do show a relative depletion of Tregs and increased Th17 cells and IL-17.[88] The functional impact of those alterations in human lupus is still not clear.

Cytokine production is altered in SLE, with decreased production of IL-2 a characteristic feature of patient T cells, as it is of individuals carrying the HLA 8.1 haplotype.[5] Although this deficiency in IL-2 was initially linked to the

often poor proliferative responses of lupus T cells stimulated with autologous or allogeneic T cells or soluble antigen, the recognition that IL-2 is important for maintenance of Tregs suggests another mechanism through which impaired production of IL-2 might contribute to immune system activation and autoimmunity.[89]

B cell regulation is also impaired in SLE, contributing to differentiation to production of autoantibodies and cytokines. The activated phenotype of SLE B cells has the potential to promote efficient presentation of specific self-antigens to T cells. It has not been entirely clear whether altered B cell function is strictly secondary to increased availability of T cell help, B cell survival, proliferation and differentiation factors, and signaling through TLRs or whether primary B cell dysfunction also contributes to autoimmunity. Recent studies characterizing the B cell repertoire by using single-cell polymerase chain reaction and cloning of individual immunoglobulin transcripts will permit improved understanding of the role of altered B cell tolerance mechanisms in the bone marrow versus secondary effects of T cell and cytokine help in generating self-reactive antibody specificities. BAFF/BLyS, IL-10, and IL-21 are among the candidate therapeutic targets that could modify the B cell differentiation program, a suggestion supported by successful clinical studies of BAFF/BLyS blockade. An additional approach toward improved regulation of B cell function is suggested by recent data demonstrating an association between vitamin D deficiency and presence of antinuclear antibodies in healthy individuals and increased B cell activation and serum type I IFN activity in vitamin D–deficient SLE patients.[90]

The baseline activation status of lupus B cells, as well as their response to antigen stimulation, is altered when compared with B cells from healthy individuals, and current studies are exploring the functional implications of lupus-associated genetic variants in several kinases, phosphatases, and adaptor molecules such as BLK, BANK, and PTPN22 for B cell function. Studies of the risk variant of *PTPN22* in B cells from healthy participants point to the influence of that lupus-associated variant on impaired counterselection of self-reactive B cells.[91] *LYN* deficiency in mice is associated with a lupus-like phenotype, and similar deficiencies in the LYN kinase have been described in lupus B cells.[92] Polymorphisms in the gene encoding Lyn studied in European-descent individuals could potentially impact B cell signaling and autoimmunity.[93] The gene encoding the inhibitory Fc receptor, *FCGR2B*, is polymorphic, and several variants have been associated with SLE.[94,95] SLE B cells show decreased expression of this FcR and altered cytokine production when engaged by immune complexes. Interestingly, the inhibitory capacity of FcγRIIb can be exploited by using an engineered bifunctional antibody that coligates CD19 and FcγRIIb. This antibody was found to suppress B cell functions in a mouse engrafted with human B cells.[96]

Current investigations of antibody-producing cells are defining several categories of B lineage cells that contribute to autoimmunity and disease. Long-lived plasma cells that are maintained by chemokines and stromal cell products in protective niches in the bone marrow are proposed as sources of those lupus autoantibodies such as anti-Smith (Sm) and anti-Ro that are chronically maintained at fairly constant levels. Those antibodies have been refractory to modulation by immunosuppressive or B cell depletion therapy.[97] In contrast, circulating preplasma cells or plasmablasts are sources of anti-dsDNA antibodies that fluctuate in some patients in association with variations in disease activity and might be more amenable to anti–B cell therapy.[98]

The T and B cell alterations that have been described in studies of lupus immune function are undoubtedly a reflection of multiple genetic variations that play out in altering threshold for cell activation and efficiency of cell signaling. They are also the result of interactions among those lymphocytes, along with antigen-presenting cells and their products, that with time amplify the overall level of immune activation. Increased production of type I IFN and presence of anti-nuclear antibodies in healthy family members of lupus patients likely reflect the consequences of genetic variations that are among the factors that predispose to SLE.[99] When the circuits of immune activation are amplified by environmental triggers, conditions are in place to generate the characteristic T and B cell autoimmunity that is required for tissue damage and disease.

## AUTOIMMUNITY IN SYSTEMIC LUPUS ERYTHEMATOSUS

Autoantibodies are traditionally viewed as essential mediators of pathology in SLE, particularly when they are in the form of immune complexes. Virtually all lupus patients demonstrate a positive anti-nuclear antibody test, and the majority of patients have one or more of the characteristic autoantibody specificities that have been associated with lupus (see also Chapter 55). Among those, anti-dsDNA and anti-Sm are most specific for SLE. Interestingly, those specificities have been linked functionally in murine studies that demonstrate that dsDNA can bind to a peptide comprising amino acids 83 to 119 of the SmD1 protein, and T cells specific for that peptide provide help for production of anti-dsDNA antibody.[100,101] Anti-Ro, anti-La, and anti-RNP antibodies are characteristic of SLE but are also seen in other systemic autoimmune diseases. These characteristic autoantibodies in SLE can be categorized in relation to their targets, including DNA and DNA-binding proteins, typically aggregated in nucleosomes that contain histones; RNA and RNA-associated proteins, typically aggregated in cytoplasmic or nuclear ribonucleoprotein (RNP) particles; phospholipids exposed in plasma membranes and associated proteins such as $\beta_2$-glycoprotein I; and cell membrane proteins, typically those expressed on blood cells. Some of these self-antigens typically targeted by lupus autoantibodies are most likely accessed by antigen-presenting cells in the form of cell membrane–enclosed blebs derived from apoptotic cells or microparticles, small aggregates of cellular material derived from cells and generated after flipping of phosphatidylserine to the outer aspect of the cell membrane in the setting of cell activation or apoptosis. Although some patients who present with a clinical picture characteristic of SLE do not have significant titers of those autoantibodies, it is likely that those patients have undefined autoimmunity targeted at unspecified antigens.

The pathogenic antibodies in SLE tend to be those produced by cells that are far along in the B cell differentiation

process, either preplasma cells or plasma cells, and have undergone immunoglobulin class switching, a process that is driven by $CD4^+$ T helper cells and in some cases by TLR ligands together with B cell differentiation factors such as IL-21 and BLyS/BAFF.[80] It is not possible to define the earliest step in the generation of pathogenic autoantibodies, and in fact it is probable that the generation of autoimmunity can begin in any number of ways. Presentation of self-antigen by an excessively activated antigen-presenting cell, stochastic activation of low-avidity self-reactive T cells that are present in healthy individuals but have the potential to expand and drive differentiation of B cells with broad specificity for self-antigens, or direct activation of self-reactive B cells in the presence of activating TLR ligands, such as those provided by demethylated CpG-rich DNA from bacteria or viruses or self-derived nuclear debris might all be starting points for development of pathogenic autoimmunity. The process might begin with production of type I IFN by a virus-infected cell or a cell with impaired degradation of intra-cellular nucleic acids, altering the threshold for activation of the immune system by subsequent exposures to self-antigens. Oxidative or UV-mediated DNA damage by environmental stressors might synergize with altered maintenance of genome integrity to jump-start immune activation. Less important than the precise starting point is the observation that autoimmunity develops and builds with time. The presence of autoantibodies can be observed more than 5 years before clinical manifestations of disease appear, and the scope of autoantibody specificities expands with time.[102] Data from analysis of the prevalence of several lupus autoantibodies among sera collected from members of the military in whom SLE developed later demonstrate an intriguing sequence. Anti-Ro antibodies typically present earliest, anti-dsDNA antibodies appear several years later, and anti-Sm, the antibody specificity most specific for a diagnosis of SLE, appears approximately at the time of clinical diagnosis. This pattern, along with studies from murine models that demonstrated determinant spreading of autoantibody specificities not only to distinct proteins within a nucleic acid–protein particle but also to other self-antigen targets, provides clues to lupus pathogenesis that are not yet understood but hold promise for future breakthroughs in elucidating important pathogenic mechanisms.[103] Additional autoantibody specificities that are associated with lupus activity and with proliferative lupus nephritis and are thought to be pathogenic include those reactive with C1q. Anti-C1q antibodies appear to recognize neoepitopes of C1q when it is bound to early apoptotic cells.[104]

A shift from a predominant polyclonal immunoglobulin (Ig)M picture toward polyclonal IgG, driven by T cell help and cytokines, occurs with time in most patients with lupus and with development of tissue pathology and damage. In fact, some IgM antibodies that have self-reactivity are viewed as protective, with the switch from IgM to IgG or IgA representing an important point of altered immune regulation that contributes to the immunopathogenesis of SLE. Some of these IgM natural antibodies react with apoptotic cells and actually inhibit their activation through TLRs.[105]

In addition to immunoglobulin class, with class-switched antibodies better able to access extravascular spaces compared with IgM antibodies, amino acid sequence and charge of the antigen-binding site can influence pathogenicity. Arginines in the CDR3 region of anti-dsDNA antibodies are characteristic and influence binding to their DNA target. Molecular mimicry is a concept that has been applied to reactivity of antibodies specific for a microbial protein that also react with self-antigens, but the concept can also be applied to those antibodies that unexpectedly bind to two distinct self-antigens. For example, some anti-dsDNA antibodies were found to bind to a peptide that is a feature of glutamate receptors on central nervous system neurons.[106] Beyond features of Ig class and antigen-binding site that influence access to tissue and affinity of binding, glycosylation and complement-fixing capacity are important determinants of the antibody's capacity to bind to Fc receptors and promote complement activation, resulting in target cell death or inflammation.

The role of SLE autoantibodies in the pathogenesis of the disease has traditionally focused on the deposition of immune complexes in skin, renal glomerulus, and other sites of tissue injury, along with a potential contribution of direct targeting of antibodies to local or "planted" antigens. But in recent years, with the recognition that nucleic acid–containing immune complexes can directly induce cell signaling and new gene transcription after accessing endosomal TLRs, an additional important pathogenic role for autoantibodies as immune modulators has been defined.

Particular lupus autoantibody specificities have been associated with specific clinical manifestations of disease (Table 79-5). Perhaps the best developed characterization of the mechanisms by which an autoantibody mediates disease is the role of maternal-derived anti-Ro antibody in the neonatal lupus syndrome. After transplacental transfer of anti-Ro antibody, RNA-containing immune complexes are thought to form, activating the production of cytokines that contribute to fibrosis of the cardiac conduction system.[107] This scenario, similar to that which mediates production of type I IFN by pDCs, identifies nucleic acid–autoantibody immune complexes as regulators of cytokine production that results in tissue damage. Anti-Ro and anti-La antibodies, although common to several autoimmune diseases, are also characteristic in association with sicca symptoms, subacute cutaneous lupus, and, as noted, in neonatal lupus. Anti-RNP antibodies are seen in both SLE and mixed connective tissue disease.

Anti-phospholipid antibodies, with lupus anticoagulant the most informative antibody profile, contribute to placental damage and vascular thrombosis, as well as thrombocytopenia in the anti-phospholipid syndrome and in some patients with lupus. Studies in a murine model indicate that tissue damage and thrombosis depend on activation of the complement system by the anti-phospholipid antibodies.[108] Similar mechanisms might be relevant in forms of lupus renal disease characterized by microangiopathy.

## MECHANISMS OF TARGET ORGAN DAMAGE

Clinical disease is ultimately a reflection of tissue damage mediated by the inflammatory sequelae of the described autoimmunity and immune system activation, along with an exaggerated or aberrant repair response. The classic view

**TABLE 79-5** Correlations Between Clinical Manifestations of Systemic Lupus Erythematosus and Autoantibodies, Immune Complexes, and T Cells

| Manifestation | Autoantibodies | Immune Complexes | T Cells |
|---|---|---|---|
| Nephritis | Anti-dsDNA<br>Anti-Ro<br>Anti-C1q<br>Ids 16/6, 3I, and GN2 | + | + |
| Arthritis | ? | + | + |
| Dermatitis | Anti-Ro<br>Anti-dsDNA<br>Id 16/6 | | + |
| Vasculitis | Anti-Ro | + | + |
| Central nervous system | Antiribosomal P<br>Antineuronal<br>Anti-NR2 | + | |

| Neonatal lupus | Anti-Ro | | |
| Sicca syndrome | Anti-Ro | | + |
| Mild disease | Anti-RNP without other autoantibody except anti-nuclear antibody | | |

RNP, Ribonucleoprotein.

of the mechanisms that result in tissue damage involves activation of the complement system by immune complexes deposited in tissue, as well as release of products of phagocytes, including enzymes released from neutrophil granules and reactive oxygen intermediates from macrophages. Recent studies in mouse and human systems involving extensive analysis of renal infiltrating cells at various points in the disease process have identified a monocyte population that has undergone differentiation to generate a functional phenotype that mediates what is apparently uncontrolled tissue repair, contributing to sclerosis and organ dysfunction.[109] Infiltrating T and B cells can also contribute to renal damage, with in situ production of autoantibodies specific for vimentin recently demonstrated.[110,111] Studies in a murine model have shown that IFN-α can also contribute to development of crescents in lupus kidneys.[112]

The role of the vasculature as a significant target organ contributing to disease in lupus has once again come to the fore, after several decades in which researchers have focused predominantly on the immune system and the contributions of autoantibodies to pathology.[113] Altered structure and function of both venous and arterial vessels have been noted for many years, including the periarteriolar concentric onion skinning seen in spleen, microangiopathy and associated microthrombi seen in some organs, and the endothelial dysfunction that has been associated with premature atherosclerosis in lupus patients. Recent studies have focused on the potential role of type I IFN on endothelial cells and endothelial cell progenitor cells, and have postulated that increased production of IFN is at least one contributor to impaired vascular repair.[114] A role for granulocytes and pro-inflammatory lipids has also been proposed.[74,115] Characterization of the micropathology of the vasculature in Degos disease, a syndrome with some common pathologic features with SLE, has drawn attention to the association of activation of the IFN pathway with vascular sclerosis and endothelial damage.[116] A possible direct contribution of type I IFN to vascular injury supplements the previously described role of complement activation products C3a and C5a and expression of endothelial cell surface adhesion molecules E-selectin, vascular cell adhesion molecule 1, and intercellular adhesion molecule 1, in lupus flares.

## CONCLUSION

Considerable gains in understanding the mechanisms of lupus pathogenesis have established the knowledge base that will underlie future advances in development of targeted therapies to achieve improved patient outcomes.[117,118] The recognition of a central role for innate immune system activation, including the role of type I IFN in lupus pathogenesis, is a major advance of recent years. Rapid progress in characterizing the genetic variants that are associated with a diagnosis of lupus has provided strong evidence that alterations in molecular pathways that regulate genome integrity, nucleic acid degradation, TLR-dependent and -independent innate immune signaling, and lymphocyte activation thresholds and signaling efficiency are important mechanisms that determine disease susceptibility. The products of the immune system, including autoantibodies and their immune complexes, cytokines, and complement components, along with pro-inflammatory mediators and reactive oxygen products released from neutrophils and macrophages, remain key mediators of tissue damage. However, an additional pathogenic role for nucleic acid–containing immune complexes as immune modulators through their important capacity to access and activate endosomal TLRs, as well as insights into regulation of endogenous cytoplasmic nucleic acids, are important new concepts that can guide future therapeutic approaches. Targeting the components of innate immune system activation that affect the TLR pathway along with modulation of pathogenic T cell help for B cell differentiation to autoantibody-producing cells, particularly that mediated by T follicular helper cells, would appear to be a rational therapeutic strategy in light of our current understanding of pathogenic mechanisms.

CHAPTER 80

# Clinical Features of Systemic Lupus Erythematosus

Maria Dall'Era • David Wofsy

**KEY POINTS**

- Systemic lupus erythematosus (SLE) is a multisystem autoimmune disease that is characterized by a relapsing-remitting course and a highly variable prognosis.
- SLE is characterized by the production of a broad array of autoantibodies. Anti-nuclear antibodies have the greatest sensitivity for the diagnosis, and anti–double-stranded DNA and anti-Smith antibodies have the greatest specificity.
- Women of childbearing age and African-American, Asian, and Hispanic populations have the highest incidence and prevalence of disease.
- Constitutional symptoms, rash, mucosal ulcers, inflammatory polyarthritis, photosensitivity, and serositis are the most common clinical features of the disease.
- Lupus nephritis is the most common of the potentially life-threatening manifestations.
- Atherosclerosis, a complication of long-standing SLE, requires aggressive risk factor modification.

Systemic lupus erythematosus (SLE) is the prototypic systemic autoimmune disease, characterized by diverse multisystem involvement and the production of an array of autoantibodies. Clinical features in individual patients can be quite variable and range from mild joint and skin involvement to severe, life-threatening internal organ disease. Criteria for the classification of SLE were initially developed by the American College of Rheumatology (ACR) in 1971, revised in 1982, and revised for a second time in 1997[1,2] (Table 80-1). A person must fulfill 4 of 11 criteria to be classified as SLE, all other reasonable diagnoses having been excluded. A patient does not have to manifest all 4 criteria simultaneously; the required 4 of 11 criteria can be fulfilled during a period of weeks or years. The ACR criteria were developed as a way to classify patients with SLE for the purpose of inclusion in clinical and epidemiologic studies. In clinical practice, these criteria are often cited to support a diagnosis of SLE. However, it should be emphasized that fulfillment of these classification criteria is not an absolute requirement for diagnosis. Rather, diagnosis typically rests on the judgment of an experienced clinician who recognizes a characteristic constellation of symptoms and signs in the setting of supportive serologic studies, after exclusion of alternative differential diagnostic possibilities. Despite widespread acceptance of the ACR criteria, several limitations affect their utility. The ACR criteria include only a subset of the various manifestations that might be present in an SLE patient. For example, despite the variety of neurologic syndromes that have been described in SLE, only seizures and psychosis are included in the ACR criteria. Proteinuria and urinary cellular casts are the only two renal criteria. Notably, a positive renal biopsy is not included in the criteria.

Against this background, the Systemic Lupus International Collaborating Clinics (SLICC) undertook an effort to revise the ACR criteria.[3] Through review of more than 700 SLE and control patient scenarios and validation in a separate sample, 17 elements were identified for inclusion into the revised criteria (11 clinical and 6 immunologic). A patient is classified with SLE if he or she (1) has biopsy-proven lupus nephritis with a positive anti-nuclear antibody (ANA) or anti–double-stranded (ds) DNA antibody or (2) fulfills four of the criteria, including at least one clinical criterion and one immunologic criterion. In contrast to the ACR criteria, the SLICC criteria would not allow a patient to be classified with SLE on the basis of clinical features alone. The revised criteria include more dermatologic and neurologic manifestations, as well as low complement levels and positive direct Coombs test in the absence of hemolytic anemia. Although the SLICC revision provides alternative criteria for use in research studies, it remains to be seen whether these criteria will ultimately replace the ACR criteria.

## EPIDEMIOLOGY

Prevalence and incidence rates of SLE vary widely in the literature. Reported prevalence frequencies range from 20 to 240 per 100,000 persons, and reported incidence rates range from 1 to 10 per 100,000 person-years.[4] This variation is partly the result of methodological differences between studies (e.g., different case definitions of SLE and methods of case ascertainment) and differing racial/ethnic compositions of the study populations. To determine more accurate and contemporary epidemiologic estimates for SLE in the United States, the Centers for Disease Control and Prevention (CDC) funded five large-scale, population-based lupus registries to conduct extensive lupus surveillance. The completed Georgia and Michigan lupus registries, composed primarily of Caucasian and African-American patients, reported incidence rates of 5.6 per 100,000 person-years and prevalences of 72.1 to 74.4 per 100,000 persons. African-American women had the highest rates. Peak disease incidence occurred during reproductive years; African-Americans had a lower mean age of onset compared with Caucasians.[5,6] Registries from California, New York, and the Indian Health Service are nearing completion and will

**TABLE 80-1** 1997 Update of the 1982 Revised American College of Rheumatology Classification Criteria for Systemic Lupus Erythematosus*

| Criterion | Definition |
|---|---|
| Malar rash | Fixed erythema, flat or raised, over the malar eminences, sparing the nasolabial folds |
| Discoid rash | Erythematous raised patches with adherent keratotic scale and follicular plugging; atrophic scarring may occur in older lesions |
| Photosensitivity | Skin rash as a result of unusual reaction to sunlight, determined by patient history or physician observation |
| Oral ulcers | Oral or nasopharyngeal ulceration, usually painless, observed by a physician |
| Arthritis | Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion |
| Serositis | Pleuritis-convincing history of pleuritic chest pain or rub heard by a physician or evidence of pleural effusions *or* pericarditis-documented by electrocardiogram or rub or evidence of pericardial effusion |
| Renal disorder | Persistent proteinuria >0.5 g/day, >3+ if quantification not performed *or*<br>cellular casts: may be red blood cell, hemoglobin, granular tubular, or mixed |
| Neurologic disorder | Seizures: in the absence of offending drugs or known metabolic derangements (e.g., uremia, acidosis, electrolyte imbalance) *or*<br>Psychosis: in the absence of offending drugs or known metabolic derangements (e.g., uremia, acidosis, electrolyte imbalance) |
| Hematologic disorder | Hemolytic anemia with reticulocytosis *or*<br>Leukopenia <4000/mm$^3$ *or*<br>Lymphopenia <1500/mm$^3$ *or*<br>Thrombocytopenia <100,000/mm$^3$ in the absence of offending drugs |
| Immunologic disorder | Anti-DNA: antibody to native DNA in abnormal titer *or*<br>anti-Smith: presence of antibody to Sm nuclear antigen *or*<br>Positive finding of anti-phospholipid antibodies based on (1) abnormal serum concentration of immunoglobulin (Ig)G or IgM anti-cardiolipin antibodies, (2) positive test result for lupus anticoagulant by using a standard method, or (3) false-positive serologic test for syphilis known to be positive for at least 6 mo and confirmed by *Treponema pallidum* immobilization or fluorescent treponemal antibody absorption test |
| Positive anti-nuclear antibody | An abnormal titer of anti-nuclear antibody by immunofluorescence or an equivalent assay at any point in time and in the absence of drugs known to be associated with drug-induced lupus syndromes |

*The presence of four or more criteria is required for systemic lupus erythematosus classification. Exclude all other reasonable diagnoses.

provide robust incidence and prevalence estimates in the Asian, Hispanic, and Native-American populations. Previous studies suggest a higher prevalence of SLE in Asian and Hispanic populations.

Most patients with SLE are seen with their disease when they are between 15 and 64 years old.[7] Patients with pediatric-onset SLE (<16 years old) are more likely to be African-American than patients with later-onset SLE.[7] SLE tends to be more severe in men and in pediatric patients. Late-onset SLE (>50 years old) is characterized by a more insidious onset, with a higher occurrence of serositis and pulmonary involvement, and a lower incidence of malar rash, photosensitivity, alopecia, Raynaud's phenomenon, neuropsychiatric disease, and nephritis.[7]

## CLINICAL FEATURES

SLE has protean clinical manifestations that may differ dramatically from patient to patient. Just as the signs and symptoms of SLE vary widely among patients, so does the severity of disease. Some patients will have relatively mild disease that is no threat to a life-sustaining organ; other patients' disease will progress rapidly to life-threatening severity.

The great variability in the expression and severity of SLE constitutes a major challenge to accurate diagnosis. Although it is difficult to pinpoint their precise frequencies, it is clear that the most common presenting manifestations are constitutional symptoms (fever, fatigue, and/or weight loss), cutaneous manifestations (e.g., malar rash), and articular manifestations (arthritis and/or arthralgia). Each of these manifestations appears to be present in at least 50% of patients with lupus at the time of diagnosis. The other clinical features of SLE are much less likely to be presenting manifestations, although virtually any of them might be the first clue to the correct diagnosis. More commonly, these manifestations appear while the disease evolves. Taken together, various descriptive studies in the literature[1,8–12] support a cumulative frequency of symptoms and signs that is summarized in Table 80-2.

### Mucocutaneous Involvement

Mucocutaneous involvement is very common in SLE. Gilliam and colleagues have categorized cutaneous lupus erythematosus (LE) lesions as "lupus specific" or "lupus nonspecific" on the basis of the histopathologic finding of interface dermatitis[13,14] (Table 80-3). In a patient with lupus, the presence of lupus-specific lesions confirms the diagnosis of cutaneous LE; lupus nonspecific lesions can occur in diseases other than lupus. Lupus-specific lesions are further subdivided into acute cutaneous lupus erythematosus (ACLE), subacute cutaneous lupus erythematosus (SCLE), and chronic cutaneous lupus erythematosus (CCLE) lesions, on the basis of additional clinical and histopathologic information. Discoid lupus is the most common subtype of

**TABLE 80-2** Frequencies of Various Manifestations of Systemic Lupus Erythematosus*

| Manifestation | Frequency (%) |
|---|---|
| Constitutional symptoms (fatigue, fever, weight loss) | 90-95 |
| Mucocutaneous involvement (malar rash, alopecia, mucosal ulcers, discoid lesions, etc.) | 80-90 |
| Musculoskeletal involvement (arthritis/arthralgia, avascular necrosis, myositis, etc.) | 80-90 |
| Serositis (pleuritis, pericarditis, peritonitis) | 50-70 |
| Glomerulonephritis | 40-60 |
| Neuropsychiatric involvement (cognitive impairment, depression, psychosis, seizures, stroke, demyelinating syndromes, peripheral neuropathy, etc.) | 40-60 |
| Autoimmune cytopenia (anemia, thrombocytopenia) | 20-30 |

*Systemic lupus erythematosus is a heterogeneous disease that can affect virtually any organ system in variable ways.

**Figure 80-1** Localized acute cutaneous lupus erythematosus (malar rash, butterfly rash). This lesion is characterized by macular or papular erythema in a malar distribution, sparing the nasolabial folds.

CCLE. SCLE and CCLE can occur as distinct isolated entities or as one of several manifestations of SLE. The risk of SLE varies with each cutaneous subset. One study of 161 patients with lupus-specific lesions showed that the classification criteria for SLE were present in 72% of patients with ACLE, 58% with SCLE, 28% with any form of discoid lupus, and 6% with localized discoid lupus confined to the head and neck. Many patients displayed more than one type of cutaneous lesion.[15]

### Acute Cutaneous Lupus Erythematosus

ACLE lesions can be localized or generalized. The hallmark feature of ACLE is localized to the malar region ("butterfly rash") and is characterized by confluent, macular, or papular erythema that last days to weeks, and appearing symmetrically on the cheeks and bridge of the nose. They do not appear on the nasolabial folds, which are sun-protected areas (Figure 80-1). Induration and scaling may occur.

**TABLE 80-3** Gilliam Classification of Skin Lesions Associated with Lupus

A. Lupus erythematosus (LE)-specific skin lesions
   1. Acute cutaneous LE (ACLE)
      Localized ACLE
      Generalized ACLE
   2. Subacute cutaneous LE (SCLE)
      Annular SCLE
      Papulosquamous SCLE
   3. Chronic cutaneous LE (CCLE)
      Classic discoid LE (DLE): (a) localized; (b) generalized
         Hypertrophic DLE/verrucous DLE
         Lupus panniculitis/profundus
         Mucosal DLE
         LE tumidus
         Chilblain LE
      Lichenoid DLE (DLE-lichen planus overlap)

B. LE-nonspecific skin lesions
   1. Cutaneous vascular disease
      Vasculitis
         Leukocytoclastic vasculitis
         Polyarteritis nodosa–like
         Vasculopathy
            Degos disease–like
            Atrophe blanche–like
            Periungal telangiectasia
            Livedo reticularis
            Thrombophlebitis
            Raynaud's phenomenon
            Erythromelalgia
   2. Nonscarring alopecia
      "Lupus hair"
      Telogen effluvium
      Alopecia areata
   3. Sclerodactyly
   4. Rheumatoid nodules
   5. Calcinosis cutis
   6. LE-nonspecific bullous lesions
   7. Urticaria
   8. Papulonodular mucinosis
   9. Cutis laxa/anetoderma
   10. Acanthosis nigricans (type B insulin resistance)
   11. Erythema multiforme (Rowell's syndrome)
   12. Leg ulcers
   13. Lichen planus

Erythema also commonly occurs on the forehead, eyelids, chin, and neck. The malar rash of SLE can be mimicked by a variety of other facial rashes, including acne, rosacea, seborrheic dermatitis, perioral dermatitis, atopic dermatitis, and erysipelas. If the diagnosis remains uncertain after an extensive clinical and serologic evaluation, biopsy of the rash can help to distinguish cutaneous lupus from other dermatologic conditions. It is important to remember that other forms of lupus-specific skin lesions, such as discoid lupus, can also occur in the malar distribution.

The generalized form of ACLE refers to widespread macular or maculopapular erythema occurring in a photosensitive distribution on any area of the body. The palmar surfaces, dorsa of the hands, and extensor surfaces of the fingers are commonly involved. In contrast to Gottron's

**Figure 80-2** Subacute cutaneous lupus (papulosquamous variant). Lesions typically appear on the back, neck, shoulders, and extensor surfaces of the arms, and usually spare the central area of the face. Lesions heal without scarring.

papules of dermatomyositis, the erythema of ACLE spares the metacarpophalangeal joints, and typically is located between the interphalangeal joints. In severe forms of ACLE, a widespread bullous eruption similar to toxic epidermal necrolysis (TEN) can occur. ACLE lesions heal without scarring, although temporary postinflammatory hyperpigmentation may be observed.

### Subacute Cutaneous Lupus Erythematosus

Subacute cutaneous lupus erythematosus (SCLE) is characterized by the presence of nonscarring, photosensitive lesions that can take one of two distinct forms: (1) papulosquamous lesions that resemble psoriasis, or (2) annular-polycyclic lesions with peripheral scale and central clearing (Figure 80-2). These two forms can occur concurrently in the same patient. SCLE has a predilection for the back, neck, shoulders, and extensor surfaces of the arms and usually spares the central face. The lesions typically last for weeks to months and heal without scarring. Rarely, a severe TEN-like eruption can evolve from SCLE lesions after sun exposure.[16] SCLE, particularly the annular subtype, is strongly associated with the presence of anti-SS-A/Ro antibody.[17] Several drugs are known to induce SCLE: angiotensin-converting enzyme inhibitors, terbinafine, hydrochlorothiazide, and calcium channel blockers are common culprits. Finally, SCLE has been implicated as a paraneoplastic syndrome.[18]

### Chronic Cutaneous Lupus Erythematosus

CCLE refers to a variety of subtypes of photosensitive lesions that can lead to skin atrophy and scar and that may persist for several months or years. Discoid lupus (DLE) is the most common subtype of CCLE. DLE is subdivided into localized discoid lupus (limited to head and neck) and generalized discoid (occurring above and below the neck) (Figures 80-3 and 80-4). The term "discoid" refers to the sharply demarcated disk-shaped appearance of the lesions, which are raised, erythematosus plaques with adherent

**Figure 80-3** Discoid lupus erythematosus on the face and scalp. Discoid lesions are a form of chronic cutaneous lupus and are commonly found on the scalp, face, and external ears. If untreated, these lesions can lead to permanent alopecia and disfigurement.

**Figure 80-4** Discoid lupus erythematosus on the dorsa of the hands. The lesions spare the proximal interphalangeal joints, a characteristic feature of lupus-specific rashes.

scales that commonly occur on the patient's scalp, face, and neck. The cheeks, nose, ears, and upper lip are classic locations for lesions. Typically, a raised, erythematous border denotes the actively expanding component. Follicular plugging is a characteristic finding. Left untreated, DLE can result in permanent alopecia and disfigurement. Squamous cell carcinoma has been described as a sequela of long-standing DLE; thus active surveillance of known lesions and

evaluation of changing lesions are critical.[19] Other subtypes of DLE include mucosal DLE (described in a subsequent section) and hypertrophic LE. Hypertrophic LE consists of chronic, indurated lesions that are covered by hyperkeratotic, multilayered scales. These lesions can be a source of diagnostic confusion because they may visually and histologically resemble squamous cell carcinoma.[20]

Other forms of CCLE include lupus panniculitis/profundus, chilblain lupus, and lupus tumidus. Lupus panniculitis is a lobular panniculitis that has a predilection for the scalp, face, arms, buttocks, and thighs. The lesions can result in depressed, sunken areas. When a cutaneous discoid lesion overlies the panniculitis, the entity is referred to as *lupus profundus*.[21] Biopsy is often necessary to secure the diagnosis because reports have described cases of T cell lymphoma that mimic panniculitis. However, biopsy should be performed carefully because the lesions have a tendency to break down. Lupus panniculitis is one of the few panniculitides that can occur above the waist. Lupus panniculitis is associated with a low risk of concomitant SLE. Chilblain lupus manifests as tender, erythematous, or violaceous papules or plaques occurring on acral areas, especially the fingers, toes, heels, nose, and ears. The lesions are brought on by cold, damp air. Chilblains lupus is more likely than idiopathic chilblains to be present even in warm weather.

Lupus tumidus lesions are characterized by edematous, erythematous plaques with a smooth surface. These lesions are highly photosensitive and have a predilection for the zygomatic region of the face. The epidermis is not involved; thus there is a lack of overlying scale or follicular plugging.

### Other Systemic Lupus Erythematosus Skin Lesions

Lupus-nonspecific skin lesions such as cutaneous leukocytoclastic vasculitis, bullous lesions, periungual erythema, and livedo reticularis can develop in patients with SLE. Cutaneous leukocytoclastic vasculitis most commonly presents as palpable purpura on the lower extremities. Bullous lupus erythematosus is a rare cutaneous manifestation characterized by subepidermal vesiculobullous skin changes, manifested by a nonscarring bullous eruption[22] (Figure 80-5). SLE may be associated with other bullous disorders such as bullous pemphigoid and dermatitis herpetiformis. The physical examination finding of periungal erythema represents dilation of the capillaries at the base of the nail. The physician can visualize these capillaries at the patient's bedside with a dermatoscope or ophthalmoscope. Other disorders associated with periungual erythema include scleroderma and mixed connective tissue disease (MCTD). Unlike scleroderma and MCTD, SLE is not associated with capillary dropout. Livedo reticularis is characterized by an erythematous to violaceous reticular or netlike pattern of the skin. It is highly associated with anti-phospholipid antibody syndrome.

### Photosensitivity

Photosensitivity occurs frequently in SLE. In one study, photo provocation testing caused an abnormal skin reaction to ultraviolet A, ultraviolet B, or visible light in more than 90% of patients with lupus.[23] Most abnormal skin reactions occurred 1 to 2 weeks after exposure to light, and persisted for weeks to months. Photosensitive patients may report worsening of their systemic disease symptoms, such as fatigue and joint pain, following sun exposure. During evaluation of a photosensitive patient, polymorphous light eruption (PMLE) and phototoxic medications are important diagnostic considerations.[24] Accurate differentiation between PMLE and lupus is essential because PMLE is treated by ultraviolet radiation phototherapy, but this treatment makes lupus worse. PMLE can occur concomitantly in patients with known SLE.

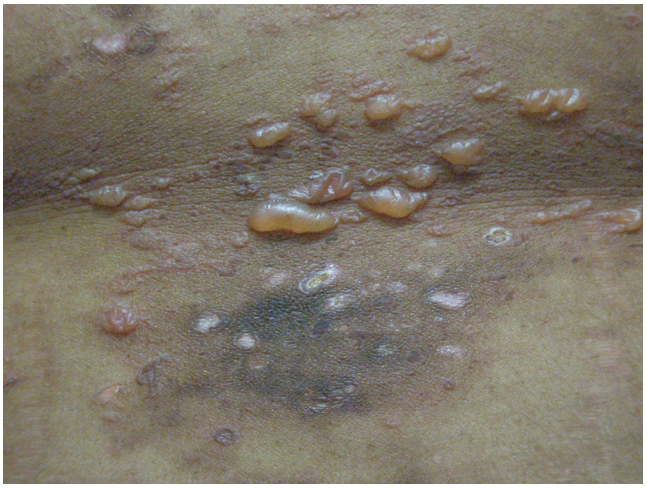

**Figure 80-5** Bullous lupus erythematosus. These lesions are a rare manifestation of lupus and are characterized by nonscarring bullous lesions.

### Alopecia

Scarring alopecia is a common complication of discoid lupus. Scalp discoid lesions most frequently develop on the vertex and parietal areas.[25] Nonscarring alopecia in patients with SLE can take several forms. "Lupus hair" is characterized by short, irregularly sized hair at the frontal hairline and is associated with active systemic disease.[26] Telogen effluvium manifests as diffuse hair thinning. Last, the incidence of alopecia areata (discrete areas of hair loss) is believed to be increased in cases of SLE.[27]

### Mucosal Ulcers

Nasal or oral lesions that represent the mucosal counterparts of cutaneous lupus commonly develop in patients with SLE.[28] Acute oral lupus lesions present as red macules, palatal erythema or petechiae, erosions, or ulcerations. These lesions are usually painless. Subacute oral lesions are rare, and are characterized by well-demarcated, round, red patches. Oral discoid lesions present as painful, well-demarcated, round, red lesions with white radiating hyperkeratotic striae. The buccal mucosa is the most commonly involved site. When the lesions evolve, they may take on a honeycomb appearance. Oral discoid lupus frequently involves the patient's lip and spreads from the vermilion border to the skin of the lip. Mucosal discoid lesions can

also occur on the conjunctiva and genital areas. In general, lupus oral ulcers have a gradual onset and can occur anywhere on the oral mucosa, with the most common locations the hard palate, buccal mucosa, and vermilion border.[29] These lesions are most commonly unilateral or asymmetric. The relationship between the presence of oral lesions and systemic disease activity remains unclear. Note that oral candidiasis and oral lichen planus can take on a similar appearance to SLE oral ulcers. The histopathology and immunopathology of mucosal lesions are similar to the alterations seen in the skin. Vasculitis is absent.

### Dermatopathology and Immunopathology

A skin biopsy is useful in the diagnosis of cutaneous lupus in the setting of an atypical clinical presentation. Immunofluorescence should always be performed, along with conventional histology. "Lupus-specific" skin lesions are characterized by an interface dermatitis consisting of a mononuclear cell infiltrate at the dermal-epidermal junction. Other pathologic findings present in lupus skin lesions include basal layer vasculopathic degeneration of keratinocytes, perivascular and periadnexal inflammation, follicular plugging, mucin deposition, and hyperkeratosis. These findings occur to different degrees in various lupus-specific skin lesions; discoid lesions show the most profound changes.[30] In contrast, early ACLE lesions may have minimal histopathologic findings and only a sparse lymphocytic infiltrate.

Immunofluorescence demonstrates granular deposition of immunoglobulin and complement components along the dermal-epidermal junction. Immunoglobulin (Ig)G and IgM are the most common immunoglobulin subtypes deposited. Various complement components, including C3, C1q, and the membrane attack complex, have also been identified. Direct immunofluorescence (DIF) of nonlesional, sun-exposed skin is referred to as the "lupus band test." Although a positive lupus band test is often seen in patients with SLE, this may also be seen in patients with other rheumatic diseases, as well as in healthy people. In one study, 20% of healthy young adults had a positive DIF in sun-exposed skin.[31] It is important to note that serologic testing with ANA, anti-dsDNA, and anti-Smith (anti-Sm) has largely supplanted use of the lupus band test in confirming the diagnosis of SLE. DIF of nonlesional, sun-protected skin is believed to be more specific for SLE.

## Musculoskeletal Involvement

### Arthritis

Arthritis and arthralgias are very common manifestations of SLE, present in as many as 90% of patients at some point during the course of their disease.[32] Severity of involvement can range from mild joint pain to deforming arthritis. Although any joint can be involved, lupus arthritis is characterized by a symmetric, inflammatory arthritis that predominantly affects the knees, wrists, and small joints of the hands.[33] Synovial effusions are typically small and not as inflammatory as those present in rheumatoid arthritis (RA). Hand deformities can occur as a result of ligamental and/or joint capsule laxity and joint subluxation. This manifestation is referred to as *Jaccoud's-like arthropathy* because it resembles the arthropathy that develops in patients with rheumatic fever (Figure 80-6). These deformities are typically reducible, although sometimes they can become fixed and are associated with disability. Jaccoud's-like arthropathy sometimes occurs in the foot, also.[34]

**Figure 80-6** Jaccoud's-like arthropathy. These hand deformities resemble those that develop in patients with a history of rheumatic fever and are caused by ligamentous and/or joint capsule laxity. Deformities in the hands, such as ulnar drift at the metacarpophalangeal joints, swan neck and boutonnière deformities, and hyperextension at the interphalangeal joint of the thumb, closely resemble the deformities seen in rheumatoid arthritis. The absence of erosions on radiographs and their reducibility distinguish this condition from the deforming arthritis of rheumatoid arthritis. *(Courtesy Dr. D. Vassilopoulos.)*

Although lupus arthritis is not classically associated with erosions on plain radiography, erosive disease has been described in a small subset of patients.[35] In addition, MRI studies have shown occasional erosions in some patients with lupus arthritis.[36] A subset of patients with SLE who also meet classification criteria for RA have historically been referred to as "rhupus." One study demonstrated the presence of marginal joint erosions on plain radiography in 60% of such patients [37] Erosive arthritis is commonly a feature of MCTD. Some studies have demonstrated an association between lupus erosive arthritis and the presence of anti-citrullinated protein antibodies (ACPA).[35] In addition to arthritis, tendinitis or tenosynovitis is frequently observed in patients with SLE.[38] Tendon rupture is a very uncommon occurrence.

Synovial biopsies from patients with lupus arthritis have shown a variety of abnormalities, including deposition of fibrin-like material, focal or diffuse synovial lining cell proliferation, vascular congestion, perivascular mononuclear cell infiltration, vasculitis, and obliteration of vessel lumina.[39] Radiographic studies of patients with SLE have revealed changes such as cystic bone lesions, periarticular soft tissue swelling, demineralization, acral sclerosis, joint subluxations, and erosions.[40,41]

### Avascular Necrosis

Avascular necrosis (AVN), also referred to as *aseptic necrosis* and *ischemic necrosis*, is a painful and disabling condition that occurs in some patients with SLE.[42] AVN is the end result of interruption of the blood supply to bone, leading to reactive hyperemia of adjacent bone,

demineralization, and then collapse. The most commonly affected sites include the femoral heads, tibial plateaus, and femoral condyles, but smaller joints can be involved as well. AVN is often bilateral, and joint effusions may occur. AVN of the femoral head should be suspected in a patient with SLE who has groin pain that is worsened with weight bearing and movement of the hip. The pain may radiate down the side of the thigh, and a limp might be evident. Although both plain radiographs and MRI can be helpful in the diagnosis of AVN, MRI is the more sensitive test. One prospective MRI study of 45 patients with SLE on glucocorticoid therapy demonstrated that silent osteonecrosis of the femoral head developed in 34% of patients.[43] However, MRI studies may be too sensitive an indicator, in that some lupus patients with suggestive MRI findings never progress to clinical symptoms of AVN. Therefore MRI findings should always be interpreted in the context of the clinical setting. The use of high doses of glucocorticoids is a well-known risk factor for AVN, but AVN has also been described in patients with SLE who have never used glucocorticoids. An MRI study of 72 newly diagnosed patients with SLE demonstrated that AVN typically developed within the first 3 months of initiation of high-dose glucocorticoids.[44] Epidemiologic studies have shown that high disease activity, as measured by the Systemic Lupus Erythematosus Disease Activity Index (SLEDAI), and the use of cytotoxic medications are also associated with AVN.[45,46]

### Myositis

Although myalgias occur commonly in SLE, true myositis is relatively rare. One study of patients with SLE at the National Institutes of Health (NIH) found a prevalence of myositis of 8%.[47] In most of those patients, myositis was one of the presenting features of SLE. Myositis usually involves the proximal upper and lower extremities. Histologic findings in SLE myositis are often less pronounced than those observed in polymyositis.

A biopsy study of 55 unselected patients with SLE demonstrated that several pathologic changes, including type II fiber atrophy, lymphocytic vasculitis, and myositis, were increased in patients with SLE compared with control patients.[48]

It is important to distinguish myositis secondary to SLE from drug-induced myopathies caused by glucocorticoids, antimalarial agents, colchicine, or statins because the treatment is very different. Muscle enzymes such as creatine phosphokinase (CPK) and aldolase are typically normal in patients with both glucocorticoid- and hydroxychloroquine-induced myopathy. Biopsy specimens usually reveal characteristic findings, including vacuolar changes in hydroxychloroquine myopathy and type II fiber atrophy in glucocorticoid myopathy in the absence of inflammation. Colchicine can result in a myopathy or neuromyopathy with elevation of serum CPK levels. Muscle histology reveals a vacuolar myopathy. Finally, it is important to think broadly about other potential causes of myopathy and myositis in patients with SLE, including thyroid disease, electrolyte abnormalities, and infectious myositis. One must also consider the possibility of MCTD because myositis can be a prominent feature of that disorder.

## Renal Involvement

### General Considerations

Renal involvement is common in SLE and is a significant cause of morbidity and mortality.[49,50] It is estimated that as many as 90% of patients with SLE will have pathologic evidence of renal involvement on biopsy, but clinically significant nephritis will develop in only 50%. The clinical presentation of lupus nephritis is highly variable, ranging from asymptomatic hematuria and/or proteinuria, to frank nephrotic syndrome, to rapidly progressive glomerulonephritis with loss of renal function. Lupus nephritis typically develops within the first 36 months of the disease, although there are exceptions. Thus periodic screening for the presence of nephritis is a critical component of the ongoing evaluation and management of patients with SLE. Routine screening procedures include inquiry about new-onset polyuria, nocturia, or foamy urine, and examination of the patient for the presence of hypertension or lower extremity edema. It is important to screen at regular intervals for the presence of proteinuria and/or hematuria and a change in serum creatinine. In patients with active SLE, screening at 3-month intervals is prudent.

### Types of Renal Involvement in Systemic Lupus Erythematosus

Several forms of renal involvement have been described in SLE, including immune complex–mediated glomerulonephritis (the most common form), tubulointerstitial disease, and vascular disease. Glomerulonephritis is characterized by immune complex deposition and inflammatory cell infiltration into the glomerulus. The pattern of glomerular injury is primarily related to the site of immune complex deposition. Tubulointerstitial and vascular disease can occur with or without immune complex–mediated glomerulonephritis. Tubulointerstitial disease has been observed in as many as 66% of SLE renal biopsy specimens[51] and is characterized by inflammatory cell infiltrates, tubular damage, and interstitial fibrosis. The presence of tubulointerstitial disease is a strong predictor of poor long-term renal outcome.[52]

Renal vascular lesions in SLE include "lupus vasculopathy," thrombotic microangiopathy (TMA), vasculitis, and nonspecific vascular sclerosis.[53,54] Lupus vasculopathy is defined as the presence of immunoglobulin and complement-containing thrombi within the glomerular capillary or arteriolar lumina. Inflammatory changes to the vascular wall are absent. TMA is characterized by the presence of fibrin thrombi within the glomerular capillary or arteriolar lumina and may be associated with the presence of antiphospholipid antibodies. The finding of TMA should prompt consideration of anti-phospholipid antibody syndrome nephropathy (APSN). The frequency of TMA was 24% in a study of 148 patients with biopsy-proven lupus nephritis.[55] The majority of patients with documented TMA were thought to have renal-limited TMA in that there was no identifiable alternative disease process to explain the TMA, such as thrombotic thrombocytopenic purpura hemolytic uremic syndrome (TTP-HUS), malignant hypertension, or the presence of anti-phospholipid antibodies. The patients with concomitant biopsy-proven lupus nephritis and TMA

had higher levels of proteinuria, higher serum creatinine concentrations, and a worse renal prognosis. Although exceedingly rare, true vasculitis characterized by leukocyte infiltration and fibrinoid necrosis of arterial walls can occur. Nonspecific sclerotic vascular lesions characterized by fibrous intimal thickening are commonly observed. The presence of such vascular lesions is associated with decreased renal survival.[56] In one study of 341 patients with lupus nephritis, renal vascular lesions were identified in 82% of patients. Vascular immune deposits were the most common lesion observed (74% of patients).[57] In addition to the lupus-related renal lesions described previously, unrelated renal abnormalities may develop in patients with SLE. Such pathologic lesions include focal segmental glomerulosclerosis (FSGS), hypertensive nephrosclerosis, diabetic nephropathy, and thin basement membrane disease.[58] In an SLE patient in whom renal disease is suspected, renal biopsy is critical in distinguishing between these potential causes and in guiding appropriate management decisions.

## Laboratory Evaluation

### Urinalysis

A urinalysis with microscopy is essential in the screening and monitoring of lupus nephritis.[59] Hematuria, pyuria, dysmorphic red blood cells, red blood cell casts, and white blood cell casts may all be present. Red blood cell casts are very specific, but not sensitive, for the diagnosis of glomerulonephritis. Early morning urine specimens, which tend to be concentrated and acidic, are ideal for the detection of red blood cell casts. White blood cells, red blood cells, and white blood cell casts may indicate the presence of tubulointerstitial involvement. Hematuria in the absence of proteinuria might be to the result of urolithiasis, menstrual contamination, or bladder pathology, particularly transitional cell carcinoma in a patient with previous cyclophosphamide exposure.

Accurate measurement of proteinuria is critical because proteinuria is a very sensitive indicator of glomerular damage. In addition, studies of chronic kidney disease have shown that the magnitude of proteinuria is a strong predictor of glomerular filtration rate decline.[60] Normal daily protein excretion is less than 150 mg. Although the gold-standard tool is an accurately collected 24-hour urine protein, this test can be cumbersome for patients and is prone to errors in undercollection and overcollection. Thus many clinicians are currently using the random spot urine protein-to-creatinine ratio for convenience. Use of the spot ratio is controversial because data suggest that the spot ratio often is not representative of the findings in a timed collection, especially in the range of 0.5 to 3.0 (the range of most lupus nephritis flares).[61] However, a spot ratio can be a helpful screening test for the presence of proteinuria, and is useful in differentiating nephrotic from non-nephrotic range proteinuria.[62] A urine dipstick should not be used for the quantification of proteinuria because it reflects protein concentrations and varies depending on the volume of the sample. Many experts currently recommend calculation of the protein: creatinine ratio from a 12- or 24-hour urine collection as the gold standard of proteinuria assessment.[63]

### Measurement of Renal Function

Although easy to measure, serum creatinine is a fairly insensitive indicator of early decline in glomerular filtration rate (GFR). Creatinine is freely filtered across the glomerulus and is also secreted by the proximal tubule. While GFR falls, the rise in serum creatinine is counteracted by increased tubular creatinine secretion. In addition, hemodynamic changes, such as those caused by treatment with angiotensin-converting enzyme inhibitors or nonsteroidal anti-inflammatory drugs, are a common cause of changes in serum creatinine levels in the absence of progression of underlying renal disease. However, trending serum creatinine during a period of time is a reasonable method by which to follow a patient's renal function. Many clinicians prefer to utilize equations that estimate GFR, such as the Modification of Diet in Renal Disease (MDRD) or the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) study equations. The CKD-EPI equation is more accurate than the MDRD equation in patients with higher GFRs. Whichever method is chosen, the detection of changes in renal function during a period of time is more important than the absolute level when following lupus nephritis patients in clinical practice.

### Renal Biopsy

When a patient with SLE has clinical or laboratory features that suggest the presence of nephritis, a renal biopsy should be performed to confirm the diagnosis, evaluate the degree of disease activity, and determine an appropriate course of treatment. The importance of renal biopsy was emphasized in the ACR's guidance document for the case identification, treatment, and monitoring of lupus nephritis.[64] According to this document, biopsy is highly recommended for patients who meet any of the following criteria: (1) increasing serum creatinine without compelling alternative causes, (2) confirmed proteinuria of greater than or equal to 1 g/24 hours, (3) proteinuria greater than 0.5 g/24 hours plus hematuria, or (4) proteinuria greater than 0.5 g/24 hours plus cellular casts. Proteinuria can be measured by a 24-hour collection or spot protein to creatinine ratio.

Before renal biopsy, ultrasonography is recommended to assess kidney size and structure and to rule out renal vein thrombosis. Kidney size of less than 75% of normal is a relative contraindication to biopsy.[65] SLE glomerulonephritis is classified by the International Society of Nephrology/Renal Pathology Society (ISN/RPS) into six categories on the basis of light microscopic, immunofluorescent, and electron micrographic findings[66] (Table 80-4 and Figure 80-7).

An individual biopsy might exhibit just one of the ISN/RPS pathologic classes or a combination of classes. Class I is characterized by normal-appearing glomeruli on light microscopy and mesangial immune deposits on immunofluorescence. Class II is characterized by mesangial proliferation on light microscopy and mesangial deposits on immunofluorescence. Class III and IV lupus nephritis lesions are highly inflammatory and are characterized by immune complex deposition in the subendothelial space. They have traditionally been described as "proliferative" because of the presence of proliferating endocapillary cells within the glomeruli. They are believed to be inter-related lesions that

**TABLE 80-4** International Society of Nephrology/Renal Pathology Society Classification of Lupus Nephritis

| WHO Type | |
|---|---|
| Class I | **Minimal Mesangial Lupus Nephritis**<br>Normal glomeruli by light microscopy, but mesangial immune deposits by immunofluorescence |
| Class II | **Mesangial Proliferative Nephritis**<br>Purely mesangial hypercellularity of any degree or mesangial matrix expansion by light microscopy, with mesangial immune deposits<br>Few isolated subepithelial or subendothelial deposits may be visible by immunofluorescence or electron microscopy, but not by light microscopy |
| Class III | **Focal Lupus Nephritis**<br>Active or inactive focal, segmental, or global endocapillary or extracapillary glomerulonephritis involving <50% of all glomeruli, typically with focal subendothelial immune deposits, with or without mesangial alterations |
| Class IV | **Diffuse Lupus Nephritis**<br>Active or inactive diffuse, segmental, or global endocapillary or extracapillary glomerulonephritis involving ≥50% of all glomeruli, typically with diffuse subendothelial immune deposits, with or without mesangial alterations. This class is subdivided into diffuse segmental (IV-S) lupus nephritis when ≥50% of the involved glomeruli have segmental lesions, and diffuse global (IV-G) lupus nephritis when ≥50% of the involved glomeruli have global lesions. Segmental is defined as a glomerular lesion that involves less than half of the glomerular tuft. This class includes cases with diffuse wire loop deposits, but with little or no glomerular proliferation |
| Class V | **Membranous Lupus Nephritis**<br>Global or segmental subepithelial immune deposits or their morphologic sequelae by light microscopy and by immunofluorescence or electron microscopy, with or without mesangial alterations<br>Class V nephritis may occur in combination with class III or class IV, in which case both are diagnosed<br>Class V nephritis may show advanced sclerotic lesions |
| Class VI | **Advanced Sclerotic Lupus Nephritis**<br>≥90% of glomeruli globally sclerosed without residual activity |

WHO, World Health Organization.

Modified from Weening JJ, et al: The classification of glomerulonephritis in systemic lupus erythematosus revisited. *J Am Soc Nephrol* 15:241, 2004.

differ in the distribution of endocapillary immune complex deposition. Class III denotes that less than 50% of glomeruli are involved, and class IV denotes that 50% or more of glomeruli are involved. Class IV lesions are subcategorized according to whether most glomeruli show focal (<50% of the glomerular tuft) or global (≥50% of the glomerular tuft) involvement. These lesions are further described as active (A), chronic (C), or a mixture of the two (A/C). Both active and chronic lesions are taken into consideration when determining whether the designation of class III or class IV is most appropriate. Thick subendothelial immune deposits form classic "wire loop" lesions. Sometimes, wire loop lesions are present in the absence of cellular proliferation. Class V lupus nephritis is characterized by immune complex deposition in the subepithelial space, resulting in widespread thickened capillary loops. These findings are similar to those observed in idiopathic membranous nephritis. However, the presence of concomitant mesangial deposits, C1q deposition on immunofluorescence, or tubuloreticular inclusion bodies would favor the diagnosis of lupus. This lesion is commonly manifested clinically as nephrotic range proteinuria. Class V nephritis may occur in a pure histopathologic form or in combination with features of class III or class IV nephritis. Class VI nephritis is defined by the presence of more than 90% globally sclerotic glomeruli. In addition to the type of glomerular pathology, the ISN/RPS classification system dictates that tubulointerstitial disease and/or vascular disease should be noted on the diagnostic line. However, it is important to note that the class of lupus nephritis is based entirely on the glomerular pathology.

Immunofluorescence studies are an important supplement to the findings on light microscopy. Immunofluorescence reveals the type and pattern of immune complex deposition. Lupus nephritis is characterized by a granular pattern of immunofluorescence along the glomerular basement membrane, mesangium, and/or tubular basement membranes. The characteristic findings of lupus nephritis are sometimes referred to as the "full-house" pattern, because IgG, IgM, IgA, C3, and C1q are all found in the deposits. Electron microscopy is useful in more precisely localizing the sites of immune complex deposition. The finding of tubuloreticular inclusion bodies within endothelial cells is strongly suggestive of the diagnosis of lupus nephritis. However, because tubuloreticular inclusion bodies are associated with increased levels of interferon (IFN)-α, chronic viral infections such as hepatitis B/C and HIV must be ruled out.

Renal biopsy is especially important because urinary parameters such as hematuria and the degree of proteinuria imperfectly predict the underlying renal pathology.[67,68] For example, hematuria might be absent in patients with severe class IV nephritis, and proteinuria can be modest in patients with class V nephritis. A repeat renal biopsy may be indicated in certain clinical settings (e.g., if a patient is not responding appropriately to therapy, if a patient unexpectedly worsens after having achieved a good response to therapy, or to determine whether residual proteinuria after a course of treatment is the result of ongoing active lupus nephritis vs. glomerulosclerosis). Repeat renal biopsy can be useful in detecting class transformation that occurs in 15% to 50% of lupus nephritis patients during the course of their disease. Class transformation can occur spontaneously or as a result of treatment.

## Outcome

Each ISN/RPS histopathologic class portends a distinct renal prognosis. Patients with class I and class II nephritis have an excellent renal prognosis and do not require any specific therapy. In contrast, the long-term renal prognosis of class III or class IV nephritis is poor in the absence of immunosuppressive therapy. Although the long-term renal prognosis of class V nephritis is more favorable than that of class III or class IV nephritis, class V patients are more likely to suffer from morbid complications of the nephrotic syndrome, including cardiovascular disease, thromboembolic disease, and hyperlipidemia. Several epidemiologic studies

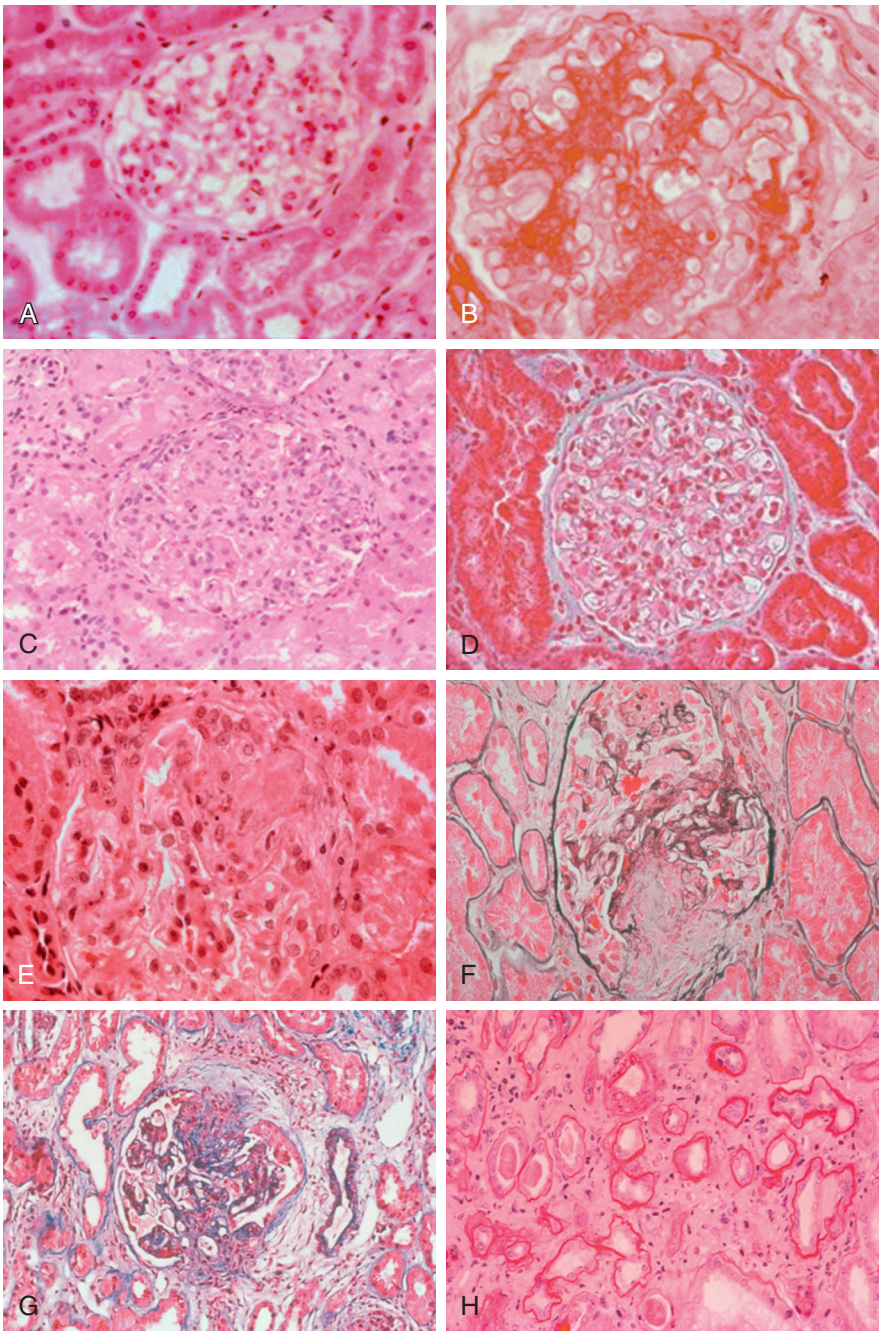

**Figure 80-7** **A** through **D**, World Health Organization types of lupus. (See Table 80-4 for a detailed description of histologic findings.) **A**, Normal glomerulus (type I). **B**, Mesangial proliferative (type II). **C**, Proliferative nephritis. Dramatic increase in mesangial and endocapillary cellularity produces a lobular appearance of the glomerular tufts and compromises the patency of most capillary loops. When less than 50% of glomeruli are involved, nephritis is denoted as focal (type III). When more than 50% of glomeruli are involved, nephritis is denoted as diffuse (type IV). **D**, Membranous nephropathy (type V). In membranous lupus nephropathy, the capillary walls of the glomerular tuft are prominent and widely patent, resembling "stiff" structures with decreased compliance. **E** through **H**, High-risk histologic features suggesting severe nephritis. **E**, Fibrinoid necrosis with karyorrhexis in a patient with focal proliferative glomerulonephritis. **F** and **G**, Cellular crescents with layers of proliferative endothelial cells and monocytes lining Bowman's capsule along with a predominantly mononuclear interstitial infiltrate. **H**, Severe interstitial fibrosis and tubular atrophy. Note the thickening of the tubular basement membranes and tubular epithelial degeneration with separation of residual tubules caused by deposition of collagenous connective tissue among tubules.

have defined demographic, clinical, and histopathologic factors associated with renal outcome in patients with lupus nephritis. Studies have shown that African-Americans and Hispanics/Latinos generally experience a worse renal prognosis than white and Chinese populations. The reasons for this disparity most likely involve a combination of genetic and socioeconomic factors.

## Pleuropulmonary Involvement

Pleuropulmonary manifestations of SLE are diverse and can involve any aspect of the lung (Table 80-5).

### Pleuritis

Pleuritis will develop in as many as 50% of patients with SLE. Clinically apparent pleural effusions are typically small, bilateral, and exudative.[69] Pleuritis is commonly manifested by pleuritic chest pain, but pleural effusions may be asymptomatic and detected on routine chest radiography performed for another purpose. Massive pleural effusions requiring pleurocentesis and/or pleurodesis are uncommon but have been reported.[70] The presence of pleuritis usually corresponds to active SLE in other organ systems.[71] Thoracoscopic evaluation has demonstrated nodules on the visceral pleura with immunoglobulin deposits detected on immunofluorescence. The differential diagnosis of pleural effusions in a patient with SLE includes infection, malignancy, and heart failure. In addition, pleural effusions are a common feature of drug-induced lupus. In the absence of infection, high levels of serum C-reactive protein (CRP) have been found to correlate well with the presence of pleuritis and other forms of serositis in SLE.[71,72]

**TABLE 80-5** Pleuropulmonary Manifestations of Systemic Lupus Erythematosus

| Manifestation | Key Features |
|---|---|
| Pleuritis | May occur with or without effusion<br>May correlate with elevated serum C-reactive protein |
| Pleural effusion | May be asymptomatic<br>Usually small, bilateral, exudative<br>Common feature of drug-induced lupus<br>Must exclude infection, malignancy, heart failure |
| Acute pneumonitis | Severe respiratory illness with fever, cough, pulmonary infiltrates, hypoxemia<br>Pleural effusion may be present<br>High mortality rate<br>Bronchoscopy with bronchoalveolar lavage might be necessary to exclude infection |
| Chronic interstitial lung disease | May develop after acute pneumonitis or in a more insidious fashion<br>Presents as dyspnea on exertion, pleuritic chest pain, nonproductive cough<br>High-resolution computed tomography is more sensitive than chest radiograph in detecting disease<br>Must exclude infection, pulmonary edema, malignancy |
| Diffuse alveolar hemorrhage | Presents as dyspnea and cough, alveolar infiltrates, fall in blood hemoglobin level<br>Hemoptysis may not be present<br>Diffusion capacity of carbon monoxide typically increased<br>Bronchoscopy with bronchoalveolar lavage confirms the diagnosis and excludes infection<br>High mortality rate |
| Pulmonary arterial hypertension | Presents as dyspnea on exertion, fatigue, chest pain, nonproductive cough<br>Diagnosis should be confirmed with right heart catheterization<br>Exclude secondary causes of pulmonary hypertension, including thromboembolic disease |
| Shrinking lung syndrome | Dyspnea, low lung volumes, elevation of hemidiaphragms in the absence of lung parenchymal involvement |

### Lupus Pneumonitis

Acute lupus pneumonitis is a rare manifestation of SLE that presents as a severe, acute respiratory illness with fever, cough, pulmonary infiltrates, and hypoxemia. Chest radiography usually reveals bilateral, lower lobe, acinar infiltrates that often occur in conjunction with a pleural effusion. Histopathologic findings are nonspecific and include diffuse alveolar damage, inflammatory cell infiltrates, hyaline membranes, and alveolar hemorrhage.[73] Immunofluorescence studies have demonstrated granular deposits of IgG and C3 within the alveolar septa.[74] Because clinical and pathologic features of acute lupus pneumonitis are nonspecific, careful evaluation is critical to exclude other potential pulmonary processes such as infection. If routine blood and sputum cultures are nondiagnostic, bronchoscopy with bronchoalveolar lavage can be useful in detecting pulmonary pathogens. A "tree and bud" pattern on high-resolution CT (HRCT) may suggest the presence of an atypical pneumonia. Acute lupus pneumonitis is associated with significant morbidity and mortality. One series of 12 patients reported a mortality rate of 50%, with deaths from respiratory failure, opportunistic infection, and thromboembolic events. Three of the surviving patients progressed to chronic interstitial pneumonitis.[75]

### Chronic Interstitial Lung Disease

Chronic interstitial lung disease is a rare manifestation of SLE. It occurs more commonly in other connective tissue diseases such as systemic sclerosis, RA, and polymyositis/dermatomyositis. Interstitial lung disease in the setting of SLE can develop after one or more episodes of acute pneumonitis but can also occur in an insidious fashion.[75] Symptoms are similar to those seen in patients with idiopathic interstitial lung disease and include dyspnea on exertion, pleuritic chest pain, and chronic, nonproductive cough. The diagnosis of interstitial lung disease is often made on the basis of clinical-radiologic findings; lung biopsy is not routinely performed. Chest radiography results might be normal early in the disease but can show reticular opacities. Pulmonary function studies show a restrictive pattern with reduction in total lung capacity and reduction in the diffusion capacity of carbon monoxide (DLCO). HRCT is more sensitive than chest radiography in detecting

interstitial lung disease and in distinguishing reversible lesions (ground-glass opacities) from irreversible fibrotic lesions. Nonspecific interstitial pneumonia (NSIP) and usual interstitial pneumonia (UIP) are the most common patterns detected on histopathology and HRCT. Before making the diagnosis of interstitial lung disease, it is important to exclude infection, pulmonary edema, and malignancy.

### Diffuse Alveolar Hemorrhage

Diffuse alveolar hemorrhage (DAH) is a life-threatening manifestation of SLE that occurs in less than 2% of patients. It is characterized by acute or subacute onset of dyspnea and cough in the setting of new alveolar infiltrates on chest radiography and a fall in blood hemoglobin level. Similar to other causes of DAH, hemoptysis is not universally present. Although most patients are too ill to undergo formal pulmonary function tests, the DLCO is typically increased in the setting of DAH because of the presence of extravascular hemoglobin within the alveoli. Bronchoscopy with bronchoalveolar lavage (BAL) is important in ruling out infection and confirming the diagnosis. Characteristic findings include visualization of blood in the airways and serosanguineous BAL fluid that does not clear with continued lavage. Hemosiderin-laden macrophages may be present in the BAL fluid. Various histopathologic patterns have been described in lupus DAH, including bland pulmonary hemorrhage, capillaritis, diffuse alveolar damage, and vasculitis of small arterioles and small muscular pulmonary arteries. DAH usually occurs in the setting of serologically and clinically active SLE, and lupus nephritis is the most common concurrent SLE manifestation. However, DAH occasionally may be the initial manifestation of SLE. Mechanical ventilation is often required,[76] and infectious complications are common. Despite aggressive therapy, the mortality rate from DAH continues to be 50%.

### Pulmonary Hypertension

Pulmonary hypertension (PH) is a rare, devastating complication of SLE that is defined as a mean pulmonary artery pressure greater than 25 mm Hg at rest on right heart catheterization. PH can be secondary to a variety of disorders, such as pulmonary disease, leading to hypoxemia, chronic thromboembolic disease, pulmonary veno-occlusive disease, or left-sided heart disease. Pulmonary arterial hypertension (PAH) is a subtype of PH that is defined by a normal pulmonary capillary wedge pressure and elevated pulmonary capillary resistance on right heart catheterization. Symptoms of PH include dyspnea on exertion, fatigue, chest pain, and nonproductive cough. Physical examination findings may include a pronounced second pulmonary heart sound, a left parasternal lift, and signs of a volume-overloaded state. Chest radiography and HRCT are important in excluding lupus pneumonitis. Chest radiography may show cardiomegaly and a prominent pulmonary artery segment. The electrocardiogram often shows right axis deviation. Pulmonary function studies demonstrate a reduction in DLCO. Although transthoracic Doppler echocardiography is an adequate screening test for PH, the diagnosis should be confirmed by catheterization of the right side of the heart. Similar to interstitial lung disease, PAH more commonly occurs in association with scleroderma and MCTD.

In a patient with SLE who has been diagnosed with PH, an evaluation must be performed for secondary causes. Ventilation and perfusion (V/Q) lung scan and/or helical CT are useful in excluding chronic thromboembolic disease. Echocardiography can rule out left heart failure and intracardiac shunting. A sleep study can be useful in ruling out obstructive sleep apnea. An evaluation for interstitial lung disease is necessary. Some studies suggest that PAH occurs more commonly in patients with Raynaud's phenomenon. Autopsy findings suggest that the pathogenesis of PAH in the setting of SLE is likely to be multifactorial, including both primary vascular and inflammatory/immune-mediated mechanisms. Macrophages and lymphocytes are present within the vascular plexiform lesions. In addition, IgG and complement are deposited within the pulmonary artery walls.

### Other

Shrinking lung syndrome occurs in a small subset of patients with SLE and should be considered when evaluating a patient with SLE who has unexplained dyspnea and pleuritic chest pain.[77,78] The syndrome is characterized by decreased lung volumes in the setting of normal lung parenchyma. The cause of the disorder remains controversial. Diaphragmatic myopathy, abnormal chest wall expansion, phrenic neuropathy, and pleural inflammation/fibrosis have been reported as possible factors. The prognosis of this syndrome seems to be good, and progressive respiratory failure is uncommon.

Although symptomatic bronchiolar disease is uncommon in SLE, abnormalities in pulmonary function studies have been reported in as many as two-thirds of patients with SLE.[79] One study of nonsmoking patients with SLE found that 24% of patients had pulmonary function studies consistent with small airway disease. Rare case reports of bronchiolitis obliterans organizing pneumonia (BOOP) in the setting of SLE have been described.[80]

Last, a syndrome known as "acute reversible hypoxemia" has been observed in patients with active SLE. This syndrome is characterized by hypoxemia and an abnormal alveolar-arterial $pO_2$ gradient in the absence of parenchymal lung disease. Pulmonary vascular endothelial cell injury and leukoagglutination secondary to complement activation is thought to be one potential mechanism

## Cardiovascular Involvement

Cardiovascular disease is a frequent complication of SLE and may involve the pericardium, myocardium, valves, and coronary arteries.

### Pericarditis

Pericarditis, with or without an effusion, is the most common cardiac manifestation of SLE, occurring in more than 50% of patients with SLE at some point during the course of their disease.[81] Pericardial effusions are usually small and asymptomatic and typically are detected on echocardiography performed for another indication. Consistent with this

observation, necropsy studies have shown that histopathologic evidence of pericarditis is much more common than clinically symptomatic disease during life.[82] Symptomatic pericarditis classically presents as sharp, precordial chest pain that is improved when the patient is in the upright position. A pericardial rub and tachycardia may be detected on cardiac auscultation. The electrocardiogram demonstrates diffuse ST segment elevation. Similar to pleuritis, pericarditis usually occurs in the setting of active SLE in other organ systems. Although rare, SLE pericarditis complicated by large effusions and tamponade physiology has been reported. Purulent effusions necessitating pericardiocentesis have also been described, but rarely. The differential diagnosis of precordial chest pain in a patient with SLE includes costochondritis, gastroesophageal reflux disease, pulmonary embolism, myocardial ischemia, pleuritis, pneumonitis, and pulmonary hypertension.

### Myocarditis

Myocarditis, an uncommon manifestation of SLE, should be suspected in a patient presenting with various combinations of the following clinical features: unexplained heart failure or cardiomegaly, unexplained tachycardia, and unexplained electrocardiographic abnormalities. Echocardiography can confirm the presence of systolic or diastolic dysfunction and/or global hypokinesis. If myocarditis is suspected, an endomyocardial biopsy may be helpful in confirming the diagnosis and excluding other causes of cardiomyopathy such as hydroxychloroquine toxicity. The distinguishing pathologic finding of hydroxychloroquine toxicity is myocyte vacuolization in the absence of active myocarditis. Histopathologic findings of SLE myocarditis include perivascular and interstitial mononuclear cell infiltration and sometimes fibrosis and scar.

### Valvular Abnormalities

Several valvular abnormalities have been described in patients with SLE, including Libman-Sacks endocarditis (also known as "atypical verrucous endocarditis"), valvular thickening, valvular regurgitation, and valvular stenosis. One transesophageal echocardiographic (TEE) study demonstrated a prevalence of valvular abnormalities of 61% in patients with SLE compared with 9% of controls, with vegetations present in 43% of patients with SLE compared with none of the controls.[83] Valvular thickening with a predilection for the mitral and aortic valves was the most common abnormality, occurring in 50% of patients with SLE. Valvular regurgitation and stenosis were detected in 25% and 4% of patients, respectively.[83] In this study, the presence and progression of valvular disease were not associated with SLE disease activity or treatment. During a follow-up period of as long as 5 years, some valvular abnormalities resolved and some new lesions occurred. The combined incidence of stroke, peripheral embolism, congestive heart failure, infective endocarditis, need for valve replacement, and death was 22% among patients with valvular disease compared with 15% in patients without valvular disease.[83]

Libman-Sacks endocarditis has been recognized in multiple pathologic studies as a characteristic valvular abnormality in SLE. Libman-Sacks verrucae typically appear as pea-sized, flat or raised, granular lesions that occur most commonly on the ventricular aspects of the mitral valve posterior leaflet.[84] The verrucae often extend onto the adjacent left ventricular mural endocardium and may lead to adherence of the leaflet and chordae tendineae to the ventricular mural endocardium, resulting in valvular regurgitation. All four valves may be involved, but recent studies suggest a predominance of left-sided lesions. The lesions are frequently clinically silent because they are typically found on the undersurface of valve leaflets, surrounded by fibrous tissue. Histologically, two types of verrucae have been described: (1) active lesions consisting of fibrin clumps with infiltrating lymphocytes and plasma cells, and (2) healed lesions consisting of dense vascularized fibrous tissue with or without calcification. Combinations of active and healed lesions also occur. Verrucae typically do not contain polymorphonuclear cells; thus the presence of such cells should prompt consideration of infectious endocarditis. Immunopathologic studies have demonstrated immunoglobulin and complement deposition in a granular pattern at the base of the valve, along the valve leaflet, and within the verruca itself. Cardiac murmurs are frequently heard in patients with SLE. They may simply result from high-flow states such as fever and anemia, or they may reflect cardiac pathology such as mitral valve prolapse or infective endocarditis. When a new murmur is evaluated, a transthoracic echocardiogram (TTE) is an appropriate first test. However, TEE should be used in the event of a nondiagnostic TTE or in a patient with suspected thromboembolic events. TEE has been shown to be superior to TTE for detection of Libman-Sacks endocarditis.[85] Although thromboembolic events are believed to be rare complications of Libman-Sacks endocarditis, one study showed that valvular heart disease detected on TTE was associated with the presence of cerebral infarcts on MRI.[86] Systematic reviews have suggested that the presence of valvular abnormalities in SLE are associated with anti-phospholipid antibody[87,88]. One study of 1656 patients with SLE determined that the odds of valvular heart disease in patients with SLE with anti-phospholipid antibodies was three times higher than in SLE patients without anti-phospholipid antibodies. The risk for valvular heart disease was greatest for patients with lupus anticoagulant or IgG anticardiolipin antibodies.[88]

### Coronary Artery Disease

Both intramural and extramural coronary artery disease is increased in patients with SLE. Necropsy studies have demonstrated fibrous intimal proliferation of small intramural coronary arteries and obstruction of these arteries with hyaline material.[89] These lesions are similar to those observed in pathologic studies of renal and central nervous system tissue in patients with SLE. The large epicardial coronary arteries may be obstructed because of arterial emboli, in situ thrombosis, vasculitis, or atherosclerotic disease. True coronary artery vasculitis is exceedingly rare. In contrast, atherosclerotic disease is a well-recognized complication of long-standing SLE.[90] Autopsy studies have demonstrated atherosclerosis in 25% to 40% of patients with SLE. One epidemiologic study demonstrated that young women with SLE have a 50-fold higher risk of myocardial infarction compared with age-matched controls.[91] A

multicenter inception cohort determined that male sex and older age at SLE diagnosis were significantly associated with the presence of atherosclerotic disease.[92] Although patients with SLE are more likely to have classic atherosclerotic risk factors such as hypertension and exposure to glucocorticoids, these risk factors alone do not fully account for the increased risk of atherosclerosis seen in patients with SLE.[93] Although the precise mechanisms of accelerated atherosclerosis in SLE are not completely understood, it is likely that an interplay between traditional cardiovascular risk factors and autoimmune related factors is important. One example of a nontraditional, autoimmune-related factor is pro-inflammatory high-density lipoprotein (piHDL) cholesterol. In the setting of inflammation, HDL can become pro-inflammatory rather than anti-inflammatory. One study demonstrated a piHDL prevalence of 45% in women with SLE compared with 20% of female patients with RA and 4% of control women.[94] In another study, piHDL was positively associated with measures of subclinical atherosclerosis.[95]A recent prospective study of 210 women with SLE was undertaken to try to develop a risk score that could be utilized to predict the presence and progression of carotid plaque.[96] As a result, the Predictors of Risk for Elevated Flares, Damage Progression, and Increased Cardiovascular Disease in Patients with SLE (PREDICTS) panel was developed. This panel comprises four novel biomarkers (piHDL function, leptin levels, soluble TNF-like weak inducer of apoptosis [TWEAK levels], homocysteine levels), and two traditional cardiovascular risk factors (age ≥48 years, history of diabetes). A high score that used the PREDICTS panel was associated with a 28-fold increased odds of baseline carotid plaque and plaque progression in women with SLE. It remains to be determined how risk profiles such as this can be utilized in clinical practice to aid in selection of preventative treatments for patients with SLE at high risk for atherosclerosis.

The possibility of coronary artery disease must be considered in any SLE patient who is seen with chest pain and/or shortness of breath, and one should have a low threshold for a functional evaluation with a cardiac stress test. Cardiac catheterization might also be necessary for diagnosis and therapeutic intervention. It is important to evaluate these patients for the presence of anti-phospholipid antibodies because coronary artery thrombosis may be a manifestation of the anti-phospholipid antibody syndrome. Evaluation for and treatment of modifiable risk factors such as obesity, smoking, hypertension, and hyperlipidemia are important in mitigating the development and progression of atherosclerotic disease.

## Neuropsychiatric Involvement

### General Considerations

Neuropsychiatric lupus (NPSLE) consists of a broad range of neurologic and psychiatric manifestations that can involve any aspect of the central or peripheral nervous system. With the intention of improving the terminology and classification of NPSLE, an ACR subcommittee categorized NPSLE into 19 distinct syndromes encompassing the central and peripheral nervous systems (CNS and PNS)[97] (Table 80-6). The extent of this classification system underscores the complexity of NPSLE. CNS disorders range from diffuse processes such as acute confusional state, headache, psychosis, and mood disorders, to more focal processes such as seizures, myelopathy, and chorea. It is notable that the ACR classification system has removed the cryptic term "lupus cerebritis" from the vernacular. Although the ACR case definitions are very helpful in providing a framework in which to study NPSLE, accurate attribution of neuropsychiatric manifestations remains challenging. It is often difficult to distinguish whether neuropsychiatric symptoms are to the result of active SLE or other factors such as infection, metabolic abnormalities, severe hypertension, adverse effects of medications, or independent neurologic or psychiatric problems. No laboratory or imaging study is sufficiently sensitive or specific to confirm the diagnosis of neuropsychiatric SLE. Instead, the diagnosis is made on a case-by-case basis and is based on a thorough clinical evaluation that is corroborated by findings (or lack thereof) on brain imaging, serologic testing, lumbar puncture, and neuropsychiatric assessment. Correct attribution to SLE or to alternative causes is essential in ensuring that appropriate treatment is administered.

**TABLE 80-6** American College of Rheumatology Classification of Neuropsychiatric Syndromes in Systemic Lupus Erythematosus

| Central Nervous System | Peripheral Nervous System |
|---|---|
| Aseptic meningitis | Guillain-Barré syndrome |
| Cerebrovascular disease | Autonomic disorder |
| Demyelinating syndrome | Mononeuropathy, single/multiplex |
| Headache | Myasthenia gravis |
| Movement disorder | Cranial neuropathy |
| Myelopathy | Plexopathy |
| Seizure | Polyneuropathy |
| Acute confusional state | |
| Anxiety disorder | |
| Cognitive dysfunction | |
| Mood disorder | |
| Psychosis | |

See reference 97.

### Pathogenesis

Multiple pathogenic mechanisms are undoubtedly involved in the various NPSLE syndromes, but in most cases, the precise pathogenesis is unknown. In addition, mechanisms are likely to vary depending upon whether the manifestation involves the CNS or the PNS. The underlying mechanisms of CNS manifestations can be grouped into two broad categories: primary injury to the vasculature and primary injury to the brain parenchyma. A combination of the two categories can also occur. Vascular injury can take several forms, including (1) damage to both large and small vessels via thromboembolic events, often as a consequence of anti-phospholipid antibodies; (2) a bland vasculopathy of small vessels characterized by vascular hyalinization,

perivascular inflammation, and endothelial proliferation; and (3) atherosclerotic lesions. In contrast, true vasculitis of cerebral blood vessels with an inflammatory infiltrate within the vessel walls is exceedingly rare. Primary injury to brain parenchyma can occur through the action of autoantibodies, cytokines, chemokines, and infiltrating cells, often in the setting of a breached blood-brain barrier. Several autoantibody subtypes are believed to play a role in some CNS manifestations of SLE. In addition to their well-established role in thrombotic events, leading to cerebral ischemia, anti-phospholipid antibodies might bind directly to neuronal cells, leading to neuronal cell damage. Anti-phospholipid antibodies have been associated with diffuse cognitive impairment, even in the absence of an ischemic event. Antiribosomal P antibodies have been associated with the CNS manifestations of psychosis, depression, and mood disorders in some studies. Although antiribosomal P antibodies are detected in only approximately 14% of patients with SLE, the specificity of these antibodies for SLE is thought to be greater than 90%.[98] Finally, a subset of anti-DNA antibodies that cross-reacts with the *N*-methyl-D-aspartate receptor (NMDAR) might be involved in cognitive dysfunction in SLE. Binding of these antibodies to neuronal cells leads to apoptotic, non-inflammatory cell death. Histopathologic studies on post-mortem human brain tissue have demonstrated multiple CNS abnormalities, including large and small multifocal infarctions, hemorrhage, bland small vessel vasculopathy, cortical atrophy, brain edema, and demyelination.

### Approach to Diagnosis

The diagnostic evaluation of a patient with potential NPSLE is tailored to the presenting neuropsychiatric manifestation. Depending on the manifestation, consultation with a neurologist and/or a psychiatrist is advised. The most important first step is exclusion of an alternative explanation for the neuropsychiatric symptoms/signs. Lumbar puncture with cerebrospinal fluid (CSF) examination is useful for exclusion of an infectious origin. Mild lymphocytic pleocytosis and elevated CSF protein are sometimes observed in CNS lupus but are not uniformly present. CSF findings are not sensitive or specific enough to confirm a diagnosis of neuropsychiatric SLE. It is important to recognize that infection is a common cause of CNS symptoms in patients with SLE who are hospitalized with altered mental status,[99] and must be rigorously ruled out. Progressive multifocal leukoencephalopathy (PML) is a rare infection that also merits consideration in a patient with SLE who is seen with symptoms of CNS dysfunction. PML occurs more frequently in patients with SLE than in patients with other rheumatic diseases, even in the absence of significant immunosuppressive therapy.[100,101] Thus, in an SLE patient with unexplained new neurologic symptoms, polymerase chain reaction (PCR) of the CSF for the presence of JC virus should be performed. In situations in which PCR is negative, a brain biopsy might be needed to confirm the diagnosis. Electromyography and nerve conduction studies are important in the setting of suspected peripheral neuropathy. Electroencephalogram (EEG) is necessary in the evaluation of seizure. Neuropsychological testing may be helpful in the setting of suspected cognitive dysfunction.

MRI is the preferred imaging modality in patients with suspected NPSLE. The most commonly noted abnormalities are small, hyperintense, T2-weighted, focal white matter lesions located in the periventricular and subcortical white matter of the frontoparietal regions of the brain. However, these findings are nonspecific and can be observed in other disease processes such as atherosclerotic vascular disease and multiple sclerosis. Other common MRI findings include cortical atrophy, ventricular dilation, cerebral edema, diffuse white matter abnormalities, gray matter abnormalities, infarction, leukoencephalopathy, and hemorrhage.[102] MRI is especially useful in detecting the presence of infarcts, hemorrhage, and myelopathy, and sometimes can help to exclude infectious conditions such as brain abscess.[102] MRI is most likely to show abnormalities in the setting of focal neurologic deficits, seizures, chronic cognitive dysfunction, and anti-phospholipid antibody–mediated disease and is less likely to show abnormalities in the setting of headache, acute confusional state, and psychiatric syndromes. A study of 74 patients with new-onset neuropsychiatric lupus found normal MRI results in 42% of patients.[103] Given the wide variety of potential MRI findings, it is critical that MRI findings (or lack thereof) are interpreted in the context of the individual patient case.

Estimates of the prevalence of NPSLE have varied widely in the literature, largely depending on the extent to which headache and/or mild cognitive abnormalities have been included in the analysis. However, the preponderance of these studies suggests that CNS manifestations predominate versus PNS manifestations. Several of the more common syndromes and associated differential diagnoses are described in the following paragraphs.

### Selected Neuropsychiatric Lupus Syndromes

Headaches are reported in more than 50% of patients with SLE, but attribution of the headache to SLE is extremely difficult. Both migrainous and tension-type headaches have been described. One meta-analysis[104] determined that the prevalence of primary headache syndromes was not different between SLE and control patients, and that headache was not related to SLE disease activity. The evaluation of headache in an SLE patient should be similar to that in a non-SLE patient and should be directed by the presence or absence of worrisome features such as fever, meningismus, altered mental status, and focal neurologic signs.

Cognitive dysfunction, manifested primarily by deficits in thinking, memory, and concentration, is increasingly recognized in patients with SLE. Some have estimated a prevalence of as much as 80%, although serious cognitive impairment is much less common. Some studies suggest that cognitive dysfunction may be associated with the presence of anti-phospholipid antibodies, but a causal relationship has not been definitively established. Documentation of the presence and extent of cognitive dysfunction via neuropsychiatric testing can be useful in establishing a baseline in a particular patient that can be followed during a period of time, particularly when a therapeutic intervention is under consideration.

Psychiatric disorders such as psychosis, depression, and anxiety can occur in SLE, and consultation with a psychiatrist is highly recommended in the evaluation of patients

with these symptoms. A patient with SLE who is seen with psychosis represents a distinct diagnostic and therapeutic challenge. The differential diagnosis includes CNS infection, primary schizophrenia, systemic metabolic abnormalities, and psychosis occurring as a side effect of glucocorticoid therapy or illicit drugs. Steroid-induced psychosis is dose dependent and typically occurs within the first 2 weeks of treatment initiation.

Although rare, demyelinating syndromes such as optic neuritis and myelitis can occur as part of the spectrum of NPSLE. Optic neuritis is characterized by pain with eye movement, central visual field loss, and a waxing and waning course.[105] Optic neuritis should be differentiated from ischemic optic neuropathy, which typically presents with acute, painless loss of vision and lack of significant improvement in vision with time.[106] Myelitis is characterized by the onset of bilateral lower extremity paresthesia, numbness, and weakness that can rapidly progress to involve the upper limbs and the muscles of respiration. A sensory level is usually noted, and autonomic involvement of the bowel and bladder is common. Bandlike pain or discomfort around the abdomen is a characteristic symptom. It is important to differentiate myelitis from other causes of myelopathy, including infection, structural spinal cord abnormalities, and vascular insult to the spinal cord. Spinal cord MRI is the critical first test. CSF examination is important to rule out infection.

The combination of optic neuritis and myelitis presents a special clinical challenge because this combination of features can occur in the setting of SLE, multiple sclerosis (MS), or neuromyelitis optica (NMO).[107] Complicating matters, the clinical presentation of anti-phospholipid antibody syndrome can mimic demyelinating disease. A thorough clinical history, MRI, CSF analysis, and serologic testing are helpful in distinguishing these entities. NPSLE and MS can have identical white matter lesions on brain MRI. Spinal cord lesions may differ in that MS spinal cord lesions usually span an area measuring less than two spinal segments, but SLE lesions are often longitudinally extensive with involvement of more than three spinal cord segments. Although oligoclonal bands may be present in the CSF of both SLE and MS patients, the absence of oligoclonal bands and the presence of a pleocytosis significantly lessen the likelihood of MS. Although a positive ANA has been described in as many as 27% of patients with MS,[108] more specific subserologies such as anti-dsDNA and anti-Sm favor the diagnosis of SLE. NMO is an autoimmune disease of the CNS characterized by episodes of optic neuritis, myelitis, or both. In the majority of patients, NMO is a relapsing disease that occurs unpredictably.[109] The diagnosis of NMO includes the presence of optic neuritis and myelitis in conjunction with two of the following three supportive criteria: presence of the NMO IgG antibody (antibody to aquaporin 4), absence of brain lesions diagnostic of MS, and longitudinally extensive myelitis on MRI.[109] Patients with the NMO antibody with some features of the disease who do not fulfill all of these diagnostic criteria are sometimes described as having "NMO spectrum disorder." The NMO antibody is present in as many as 80% of patients with NMO and has a specificity of greater than 90% for the diagnosis of NMO. SLE and NMO may occur concurrently in a given patient.

Patients with SLE are at increased risk of stroke; ischemic stroke is more common than intracerebral hemorrhage.[110] Studies have demonstrated an association between the presence of anti-phospholipid antibodies (aPL) and/or valvular heart disease and the risk of stroke.[81] Brain MRI is a critical test in the diagnosis of ischemic or hemorrhagic stroke, and magnetic resonance angiography (MRA) can detect vessel aneurysms. Echocardiography, carotid ultrasound, and electrocardiography are important diagnostic tests in the setting of suspected thromboembolic cerebrovascular disease.

A potential mimic of CNS lupus is posterior reversible encephalopathy syndrome (PRES). This syndrome was first described in a case series of 15 patients in 1996.[111] Two of the original 15 patients were known to have SLE. PRES is a clinical-radiologic syndrome characterized by headache, decreased consciousness, visual changes, and seizures in the context of posterior cerebral white matter edema. It has been associated with a variety of conditions, including hypertension, eclampsia, renal disease, immunosuppressive therapies, post–solid organ transplantation, and autoimmune disease. When PRES occurs in the setting of active SLE, it is unclear whether PRES is a manifestation of CNS lupus, or whether it is a complication of a concomitant condition such as immunosuppressive therapy, renal disease, or hypertension.

SLE is also associated with peripheral neuropathy. One large study of more than 2000 patients with SLE demonstrated a 6% prevalence of peripheral neuropathy, with 67% of the neuropathies attributable to SLE.[112] The most common type of neuropathy was a sensory or sensorimotor axonal polyneuropathy. Of the patients, 17% had biopsy-proven small-fiber neuropathy. This is an increasingly recognized subtype of peripheral neuropathy that is not included in the 1999 ACR case definitions for NPSLE. Small-fiber neuropathies affect unmyelinated C fibers, with symptoms of burning pain and paresthesias. Nerve conduction studies are normal. The diagnosis is confirmed by a skin biopsy that demonstrates decreased intraepidermal nerve fiber density. A devastating, large-fiber vasculitic neuropathy leading to mononeuritis multiplex can also develop in patients with SLE. Autonomic neuropathies, cranial neuropathies, inflammatory demyelinating polyneuropathies, and abnormalities of the neuromuscular junction resembling myasthenia gravis have also been described. When encountering a SLE patient with peripheral neuropathy, it is essential for the physician to consider and rule out non-SLE etiologies such as infections (e.g., HIV, syphilis, Lyme disease, leprosy), malignancy, endocrine disorders (e.g., diabetes mellitus, hypothyroidism), toxins (e.g., alcohol, heavy metals), vitamin deficiency (e.g., vitamins $B_{12}$, $B_6$), and drugs (e.g., hydroxychloroquine, colchicine, vitamin $B_6$ excess).

## Gastrointestinal Involvement

SLE can involve any part of the gastrointestinal system. Dysphagia is noted in as many as 13% of patients, and manometric studies have detected abnormalities of esophageal motility.[113] Decreased peristalsis is most commonly observed in the upper one-third of the esophagus. In contrast to scleroderma, involvement of the lower esophageal

sphincter is rare in SLE.[114] A variety of potential pathogenic mechanisms have been described, including muscle atrophy, inflammation of esophageal muscle, and ischemic or vasculitic damage to the Auerbach plexus.

Abdominal pain, sometimes accompanied by nausea and vomiting, has been reported in as many as 40% of patients with SLE and can be to the result of SLE-related causes, medication side effects, and non–SLE-related causes such as infection.[115] When evaluating an SLE patient with abdominal pain, it is critical for the physician to rule out non-SLE conditions. It is important to note that when patients are treated with glucocorticoids and/or other immunosuppressives, clinical signs of an acute condition in the abdomen, such as rebound tenderness, can be masked. Thus delay in diagnosis is common. SLE-related causes of abdominal pain may include peritonitis, pancreatitis, mesenteric vasculitis, and intestinal pseudo-obstruction. Although autopsy studies have revealed evidence of peritoneal inflammation in as many as 72% of patients with SLE,[115] the presence of ascites is rare. If a patient with SLE is seen with abdominal pain and ascites, paracentesis is warranted to rule out infection. Peritonitis can also occur in the setting of mesenteric ischemia, bowel infarction, and pancreatitis. Thus abdominal imaging is an important part of the initial evaluation.

Pancreatitis caused by SLE is uncommon and usually is associated with active SLE in other organs. When considering the possible diagnosis of pancreatitis, it is important to note that elevated serum amylase may be misleading—it has been observed in patients with SLE in the absence of pancreatitis.[116] Although glucocorticoids and azathioprine have been associated with the development of pancreatitis in nonpatients with SLE, these medications do not seem to play a major role in the development of pancreatitis in patients with SLE.[117] It is important to rule out non-SLE causes of pancreatitis, such as biliary disease, alcohol consumption, and hypertriglyceridemia.

Mesenteric vasculitis is a very rare manifestation of SLE. Patients with this condition can be seen with a range of symptoms, from cramping, bloating, and anorexia, to an acute condition in the abdomen with diarrhea and gastrointestinal hemorrhage. Accurate diagnosis and prompt treatment are essential to prevent the potential catastrophic complications of necrotic bowel, perforation, and sepsis. Abdominal radiography may show distention of bowel loops, thickening and thumbprinting of the bowel wall, and/or free air in the abdomen. Ultrasonography may be useful in demonstrating bowel wall edema and thickening. Abdominal CT is thought to be the most useful imaging modality for the early diagnosis of mesenteric ischemia and can demonstrate prominence of mesenteric vessels with a palisade pattern supplying dilated bowel loops, ascites, and bowel wall thickening with a double-halo sign.[118] Gastroscopy and colonoscopy can sometimes reveal findings of ischemia and ulceration. Because lupus mesenteric vasculitis typically involves the small vessels (arterioles and venules) of the bowel submucosa, mesenteric angiography is usually nondiagnostic. However, angiography can be helpful in ruling out larger vessel causes of mesenteric ischemia, such as polyarteritis nodosa, atherosclerotic disease, or thrombosis resulting from anti-phospholipid antibody disease.

Liver test abnormalities have been described in as many as 60% of patients with SLE at some point during the course of their illness, but clinically significant liver disease is rarely a direct manifestation of SLE.[119] For this reason, the presence of liver disease should prompt a search for non-SLE causes, including medications such as nonsteroidal anti-inflammatory drugs, methotrexate, and azathioprine. Abnormal liver enzymes may be caused by hepatic steatosis as a result of obesity, concomitant diabetes mellitus, or treatment with corticosteroids. Infections such as viral hepatitis, cytomegalovirus (CMV), and Epstein-Barr virus (EBV) must also be excluded. Once medications and infections have been ruled out as possible culprits, persistent liver test abnormalities should prompt an investigation with an abdominal ultrasound and possibly a liver biopsy. Lupus hepatitis is believed to be a distinct entity from autoimmune hepatitis.[120] Lupus hepatitis is typically characterized by the presence of lobular inflammation with a paucity of lymphoid infiltrates. These findings contrast with those of autoimmune hepatitis, in which periportal (interface) inflammation and dense lymphoid infiltrates predominate. Although ANA is frequently seen in both disorders, anti–smooth muscle and anti-LKM antibodies are more frequently noted in autoimmune hepatitis than in lupus hepatitis. Rarely, nodular regenerative hyperplasia complicates SLE. This disorder causes diffuse nodularity of the liver with little fibrosis and can result in portal hypertension. Nodular regenerative hyperplasia is also associated with the presence of anti-phospholipid antibodies in some patients.[121] Vascular disorders of the liver such as Budd-Chiari syndrome, hepatic veno-occlusive disease, and hepatic infarction have been described, especially in the setting of anti-phospholipid antibodies.

Other rare gastrointestinal manifestations of SLE include intestinal pseudo-obstruction and protein-losing enteropathy. Intestinal pseudo-obstruction is characterized by decreased intestinal motility caused by dysfunction of the visceral smooth muscle or enteric nervous system.[122] The small bowel is more frequently involved than the large bowel. Presenting symptoms include abdominal pain, nausea, vomiting, and abdominal distention. Patients with protein-losing enteropathy experience abdominal pain, profound pitting edema, and diarrhea in the context of hypoalbuminemia. Other causes of hypoalbuminemia, such as nephrotic syndrome from renal disease, must be excluded.

## Occular Involvement

SLE can affect the eye in a variety of ways. The most common ocular manifestation is keratoconjunctivitis sicca (KCS), which can occur in the presence or absence of secondary Sjögren's syndrome.[123] Retinal abnormalities can be detected on ophthalmoscopic examination as retinal hemorrhages, vasculitic-appearing lesions, cotton wool spots, and hard exudates. SLE retinopathy is believed to be an immune complex–mediated vasculopathy and/or the result of microthrombotic events. The presence of retinal abnormalities has been shown to correlate with lupus nephritis, CNS lupus, and the presence of anti-phospholipid antibodies.[124] Episcleritis and scleritis can occur in SLE. Uveitis is extremely rare. Discoid lupus can involve the lower eyelid and conjunctiva. Glucocorticoids and antimalarial agents, two medications commonly used for the treatment of SLE, can affect the eye. Posterior subcapsular cataracts, elevated

intraocular pressure, and central serous maculopathy are well-described complications of glucocorticoid therapy, and maculopathy is a rare but serious complication of the use of hydroxychloroquine and chloroquine. The risk of retinal toxicity is low if the daily dose of chloroquine is kept below 3 mg/kg of ideal body weight and the daily dose of hydroxychloroquine is kept at or below 6.5 mg/kg of ideal body weight.

## Hematologic Involvement

Hematologic involvement is common in SLE; all three blood cell lines can be affected. When evaluating a patient with the hematologic abnormalities as described later, it is always necessary to consider the potential of myelosuppression from medications such as methotrexate, azathioprine, mycophenolate mofetil, and cyclophosphamide. In addition, glucocorticoids are a common cause of lymphopenia and leukocytosis secondary to neutrophilia.

### Anemia

Anemia of chronic disease (ACD) is the most common anemia in SLE. It is a normochromic, normocytic anemia characterized by the presence of low serum iron, low transferrin, and normal to increased serum ferritin. ACD can coexist with anemias resulting from other processes. Autoimmune hemolytic anemia (AIHA) should be suspected in the setting of the following laboratory abnormalities: increased serum unconjugated bilirubin, increased lactate dehydrogenase (LDH), increased reticulocyte count, and reduced serum haptoglobin. The direct Coombs test is typically positive and usually is mediated by warm-reacting IgG anti-erythrocyte antibodies. The peripheral blood smear demonstrates spherocytosis. Some reports have suggested an association between AIHA and the presence of anticardiolipin antibodies.[125,126] A positive direct Coombs test can occur without hemolysis. AIHA may be the presenting manifestation of SLE, or it may predate full-blown SLE by many years.

Microangiopathic hemolytic anemia (MAHA), characterized by the presence of schistocytes on peripheral blood smear, should prompt consideration of thrombotic thrombocytopenic purpura–hemolytic uremic syndrome (TTP-HUS). TTP is a syndrome consisting of MAHA, thrombocytopenia, fever, neurologic symptoms, and renal involvement, and may be associated with SLE. Because MAHA, thrombocytopenia, neurologic symptoms, and renal involvement can also occur in catastrophic anti-phospholipid antibody syndrome (CAPS), anti-phospholipid antibodies should always be measured as part of the evaluation. Blood loss, renal insufficiency, pure red cell aplasia, and medication-induced myelotoxicity are additional potential causes of anemia in patients with SLE.

### Leukopenia

Leukopenia occurs in approximately 50% of patients with SLE and can occur secondary to lymphopenia and/or neutropenia. One study of 158 newly diagnosed, clinically active patients with SLE demonstrated that 75% of patients had lymphocyte counts lower than 1500 cells/μL, and that lymphopenia eventually developed in 93% of patients.[127] The presence of lymphocytoxic antibodies in some patients with SLE correlates with lymphopenia and with disease exacerbation.[128] Lymphopenia may be a side effect of treatment with glucocorticoids or other immunosuppressive agents. Neutropenia resulting from SLE can result from immune-mediated destruction or marrow suppression.

### Thrombocytopenia

Mild thrombocytopenia is noted in as many as 50% of patients with SLE, but severe thrombocytopenia can also occur. Thrombocytopenia can be the result of immune-mediated platelet destruction similar to immune thrombocytopenic purpura (ITP). The platelet IIb/IIIa antigen is the primary target. Thrombocytopenia can also be caused by a consumptive process such as TTP or splenomegaly. Antithrombopoietin antibodies have been found in the sera of some patients with SLE and have been correlated with lower platelet counts.[129] Chronic, low-level thrombocytopenia is a characteristic feature of the anti-phospholipid antibody syndrome. Similar to AIHA, isolated ITP may predate the development of complete SLE by several years.[130]

## Lymphadenopathy and Splenomegaly

Lymphadenopathy commonly occurs in association with active SLE and is characterized by the presence of enlarged, soft, nontender lymph nodes. Lymphadenopathy can be focal or generalized; the cervical, axillary, and inguinal regions are typically involved. Lymph node histopathology demonstrates reactive hyperplasia and varying degrees of coagulative necrosis. The presence of hematoxylin bodies is specific for SLE. Histologic features of Castleman's disease have been reported.[131] The differential diagnosis of lymphadenopathy in a patient with SLE includes infection and/or a lymphoproliferative process; lymph node biopsy is sometimes required for diagnosis. Splenomegaly can be observed in patients with SLE and may be associated with hepatomegaly. Histopathologic studies demonstrate periarterial fibrosis (onion-skin lesions). Splenic atrophy and functional asplenism have also been reported.[132]

# DIAGNOSIS

Establishing the diagnosis of SLE can be challenging because of its heterogeneous disease manifestations and waxing and waning clinical course. No clinical manifestation or laboratory test can serve as a definitive diagnostic test. Instead, SLE is diagnosed on the basis of a constellation of characteristic symptoms, signs, and laboratory findings in the appropriate clinical context. Although the ACR classification criteria (see Table 80-1) cannot always be relied upon for diagnostic purposes in individual patients, they serve as useful reminders of the wide variety of clinical features that can be seen in SLE.

## Serologic Tests

Serologic tests play an important role in the diagnosis of SLE. SLE is the prototypic systemic humoral autoimmune disease. As such, it is characterized by production of a

**TABLE 80-7** Autoantibodies and Clinical Significance in Systemic Lupus Erythematosus

| Autoantibody | Prevalence in SLE (%) | Clinical Associations |
|---|---|---|
| **Anti-nuclear Antibody** | | |
| Anti-dsDNA | 60 | 95% specificity for SLE; fluctuates with disease activity; associated with glomerulonephritis |
| Anti-Smith | 20-30 | 99% specificity for SLE; associated with anti-U1RNP antibodies |
| Anti-U1RNP | 30 | Antibody associated with mixed connective tissue disease and lower frequency of glomerulonephritis |
| Anti-Ro/SS-A | 30 | Associated with Sjögren's syndrome, photosensitivity, SCLE, neonatal lupus, congenital heart block |
| Anti-La/SS-B | 20 | Associated with Sjögren's syndrome, SCLE, neonatal lupus, congenital heart block, anti-Ro/SS-A |
| Anti-histone | 70 | Also associated with drug-induced lupus |
| Anti-phospholipid | 30 | Associated with arterial and venous thrombosis, pregnancy morbidity |

SCLE, Subacute cutaneous lupus erythematosus; SLE, systemic lupus erythematosus.

wide variety of autoantibodies, which often provide important diagnostic information[133] (Table 80-7). Studies using antigen array technologies have demonstrated the presence of over 100 different autoantibodies in patients with SLE. The hallmark serologic feature is the presence of ANAs, as reflected by a positive ANA test. The gold standard method for detecting ANA is indirect immunofluorescence by using a human epithelial cell tumor line (HEp2 cell line). With this method, the ANA test is highly sensitive; it is positive in more than 95% of people with SLE. Because of a desire for automation and cost savings, some laboratories are utilizing the enzyme-linked immunosorbent assay (ELISA) or multiplex assays as the method of testing for ANA. However, the ELISA and multiplex methods are less accurate than the immunofluorescence method, resulting in a higher false-negative rate. Positive ANA tests also occur in many other autoimmune diseases, including RA, scleroderma, polymyositis, and autoimmune thyroiditis, among others. ANAs are also detectable in low titers (<1 : 80) in many people without autoimmune disease, especially in the elderly.[134] Therefore a positive test is not sufficient to establish the diagnosis of SLE. On the other hand, a negative test can be helpful in ruling out SLE. Although ANA$^-$ SLE has been reported, it is very rare with the immunofluorescence method of testing. In those rare instances, other tests (e.g., anti-Ro/SS-A) usually confirm the presence of lupus-associated autoantibodies.[135]

Once it has been established that ANAs are present, it is important to determine which particular nuclear antigens may be the target of the autoantibodies because some of these antigen-specific responses provide great diagnostic specificity. The most important of these tests is the test for anti-dsDNA antibodies. Anti-dsDNA antibodies are present in no more than 50% to 60% of patients with SLE, so their absence does not exclude the possibility of SLE. However, the presence of these antibodies is highly specific for SLE and therefore can be very helpful in establishing a definitive diagnosis. Similarly, antibodies to the Sm antigen have great specificity for SLE, but these antibodies are present in even fewer patients with SLE (~30%). The Sm antigen is a component of extractable nuclear antigens (ENAs), a term that refers to a heterogeneous mixture of non-DNA nuclear antigens that can be "extracted" from cells in the laboratory. These antigens are primarily ribonucleoproteins that can be divided into two major subsets based on their susceptibility to digestion by ribonuclease. The ribonuclease-sensitive antigens are designated RNP. Ribonuclease-resistant antigens are designated Sm (because these antibodies were first detected in a patient named Smith). Unlike anti-Sm, anti-RNP is not specific for SLE. However, high titers of anti-RNP antibodies can be helpful in supporting the diagnosis of MCTD.[136]

Numerous other autoantibodies can be found in patients with SLE. Antibodies to cytoplasmic antigens, such as Ro and La (SS-A and SS-B), can be found in some patients with SLE. Although these autoantibodies lack both sensitivity and specificity for SLE, they sometimes are associated with distinct clinical syndromes. The best example of such a relationship involves the presence of anti-Ro antibodies in more than 90% of cases of neonatal lupus.[137,138] Anti-Ro antibodies are also seen with increased frequency in patients with SCLE.[139] Other autoantibodies may be directed against cell surface molecules or against circulating proteins. For example, antibodies to blood components can be responsible for hemolytic anemia, neutropenia, or thrombocytopenia, and antibodies to phospholipids and phospholipid binding proteins can be detected in some patients with SLE with or without anti-phospholipid syndrome (see Chapter 82). It should be noted that rheumatoid factor (anti-IgG) can be found in 15% to 20% of people with SLE, whether or not joint disease is present.[140] ACPA can also be present.

Complement consumption arising from immune complex disease may lead to hypocomplementemia in patients with SLE.[141,142] Because hypocomplementemia is rare in other diseases, its presence in a patient with SLE can provide valuable supportive evidence for the diagnosis. Moreover, because hypocomplementemia most likely reflects complement activation by immune complexes, its presence is often a sign of active disease. However, hereditary complement deficiencies may be found in patients with SLE (C1q, C2, C4), so absence of a particular complement component does not always reflect consumption.[143–145] For this reason, it is often necessary to measure more than one complement component (e.g., C3 and C4) before concluding that hypocomplementemia is to the result of active disease.

The utility of serologic tests in assessing disease activity and predicting disease flares remains a topic of controversy. In the absence of a hereditary complement deficiency, hypocomplementemia is a reliable indicator that the disease is active, but normal complement levels do not rule out active

disease. Titers of anti-dsDNA antibodies correlate with disease activity in some patients, but not in others. One recent study attempted to resolve the long-standing debate about the prognostic value of changes in lupus serology.[146] In this study, patients with clinically quiescent lupus underwent monthly monitoring for levels of anti-dsDNA, C3a, C3, C4, and CH50 to identify patients with serologically active, clinically quiescent disease. These patients were then randomly assigned to treatment with corticosteroids or placebo to determine whether treatment of serologically active disease could prevent impending clinical flares. The results were equivocal. Some patients with serologically active disease flared, and some flares were apparently prevented. However, in most control subjects, serologic deterioration was not followed by a clinical flare, and most of the flares that occurred in the original patient population that had been monitored were not preceded by serologic deterioration. Thus there remains no substitute for knowledge of a particular patient's disease pattern or whether there is an association between clinical and serologic manifestations in that patient.

## DIFFERENTIAL DIAGNOSIS

Because of the involvement of multiple organ systems and the lack of specificity of symptoms and/or signs, many systemic diseases can mimic SLE. Thus, before a diagnosis of SLE is established, a comprehensive search for infectious, malignant, and other autoimmune diseases must be undertaken.

Several viral infections can produce symptoms and signs that are present in SLE. In addition, many viral illnesses are associated with the production of autoantibodies. A careful patient history with serologic testing for the potential pathogen should help to secure the correct diagnosis. Patients with classic parvovirus B19 are seen with fever, rash, symmetric inflammatory polyarthritis, and cytopenias. Furthermore, the presence of ANA, anti-dsDNA, and hypocomplementemia has been observed in a few cases. Cytomegalovirus and EBV can mimic SLE in that patients often are seen with fatigue, cytopenias, abdominal pain, and liver test abnormalities. Patients with acute HIV infection typically are seen with fever, diffuse lymphadenopathy, and oral ulcers. Inflammatory arthritis and positive autoantibodies can develop in patients with hepatitis B and C.

Malignancy, particularly non-Hodgkin's lymphoma, can manifest with constitutional symptoms, joint pain, cytopenias (including autoimmune hemolytic anemia), lymphadenopathy, rash, and a positive ANA. Physicians must be particularly alert to the possibility of malignancy in older patients seen with new lupus-like syndromes. It is important to ensure that patients undergo appropriate malignancy screening tests.

Other autoimmune diseases such as RA, dermatomyositis, and Still's disease often share similar clinical features with SLE. Differentiating between these disorders might be difficult in early phases of the disease. Patients with RA and SLE may develop a symmetric inflammatory arthritis with a predilection for the wrists and small joints of the hands. ANA and rheumatoid factor (RF) may be elevated in both disorders, although ACPA suggests RA, and anti-dsDNA or anti-Sm suggests SLE. The photosensitive, erythematous rashes of dermatomyositis and SLE can appear clinically and histopathologically identical. A careful patient history and supporting serologies will aid in making the correct diagnosis. Physicians must also consider MCTD when evaluating a patient for possible SLE. MCTD is a syndrome characterized by a high-titer anti-RNP antibody in conjunction with clinical features that are often present in SLE, scleroderma, and/or polymyositis. Patients frequently are seen with puffy, swollen hands and Raynaud's phenomenon. In contrast to SLE, an erosive arthritis that looks very similar to RA can develop in patients with MCTD.

Careful evaluation for drug-induced lupus should be undertaken in every new patient in whom the diagnosis of SLE is suspected. This is especially important in an older person who is seen with a lupus-like syndrome. Arthralgia, myalgia, fever, and serositis are common manifestations. A wide variety of drugs have been implicated in the development of drug-induced lupus; minocycline, procainamide, hydralazine, isoniazid, IFN-α, and TNF inhibitors are well-known culprits. Hydrochlorothiazide is associated with SCLE. All of these drugs may cause a positive ANA. Minocycline is occasionally associated with anti-dsDNA antibodies and perinuclear-staining anti-neutrophil cytoplasmic antibodies (P-ANCA), and TNF inhibitors can cause positive anti-dsDNA antibodies. Anti-histone antibodies are present in more than 95% of cases of drug-induced lupus, with the exception of those cases caused by minocycline. However, anti-histone antibodies cannot be used to confirm a diagnosis of drug-induced lupus because up to 80% of idiopathic patients with SLE will also produce anti-histone antibodies.

## NEONATAL LUPUS

Neonatal lupus is a passively acquired autoimmune disease of neonates that results from transplacental passage of maternal anti-SS-A and/or anti-SS-B antibodies.[132] It can occur in mothers with SLE, in those with Sjögren's syndrome, or in patients in whom an autoimmune disease has not been diagnosed. Neonatal lupus can involve multiple organ systems, including heart, skin, liver, and the hematologic system; the most severe complications are congenital complete heart block and cardiomyopathy.[147,148] The term *neonatal lupus* stems from early observations that the skin lesions in affected newborns were similar to the lesions of SCLE.

Congenital complete heart block is associated with a neonatal mortality rate as high as 20%, and most patients will eventually require a permanent pacemaker. This complication occurs in as many as 2% of babies born to mothers who are positive for anti-Ro/SS-A and/or anti-LA/SS-B antibodies. Thus maternal antibodies are essential but not sufficient to cause disease. Once a woman has given birth to a baby with complete heart block, the risk for recurrence in a subsequent pregnancy is approximately 17%. Once a woman has given birth to a baby with cutaneous features of neonatal lupus (without heart block), the risk for heart block in a subsequent pregnancy is 18%.[149] Evidence from in vitro studies suggests that during fetal development, fetal cardiocytes undergo apoptosis that results in expression of Ro/SS-A and La/SS-B on the cell surface. Binding of anti-Ro/SS-A and/or anti-La/SS-B to fetal cardiocytes leads

to inflammatory injury and subsequently to fibrosis of the atrioventricular (AV) node and surrounding tissue. The sinoatrial (SA) node may also be involved. Prospective studies have shown that the vulnerable period for the fetal heart is between 16 and 24 weeks of gestation. Thus it is recommended that mothers with anti-Ro/SS-A and/or anti-La/SS-B antibodies undergo monitoring with fetal echocardiography beginning at 16 weeks of gestation. The hope has been that detection of early stages of heart block (first-degree and second-degree block) might allow for treatment that would prevent progression to third-degree heart block. Currently, the treatment of choice is maternal administration of a fluorinated glucocorticoid such as dexamethasone. Fluorinated glucocorticoids are preferred because of their ability to cross the placenta and enter the fetal circulation. However, treatment of incomplete fetal heart block remains controversial because the benefits have not been clearly delineated, and glucocorticoids have been associated with several fetal side effects such as intrauterine growth retardation, oligohydramnios, and adrenal suppression. Complete heart block is irreversible even with treatment, and first- or second-degree heart block may or may not reverse with treatment. Complicating matters, complete heart block can occur in the absence of preceding first- or second-degree block. In addition to conduction blocks, structural cardiac abnormalities have been observed in the setting of neonatal lupus, including, but not limited to, patent ductus arteriosus, ventricular septal defect, atrial septal defect, and patent foramen ovale. Myocarditis and pericarditis have also been described.

Rash, a common manifestation of neonatal lupus, consists of erythematous, annular lesions that resemble the annular subtype of SCLE. The rash typically occurs on the scalp, face, trunk, and extremities with a predilection for the periorbital area; it often develops after exposure of the newborn to ultraviolet light. Lesions typically occur within the first 4 to 6 weeks of life but may be present at birth. The rash is self-limiting and does not necessitate treatment. Lesions tend to resolve by 6 months of age, at which time maternal anti-Ro/SS-A and/or anti-La/SS-B antibodies are no longer present in the baby's circulation. Lesions develop in approximately 25% of babies born to anti-SSA/SS-B positive mothers. Less common manifestations of neonatal lupus include hepatic, hematologic, and neurologic involvement.[150] Hepatic manifestations include asymptomatic elevation of liver function tests, hepatitis, hepatomegaly, cholestasis, and cirrhosis. Hematologic manifestations include thrombocytopenia, autoimmune hemolytic anemia, and leukopenia. Neurologic complications, including myelopathy, seizures, and aseptic meningitis, have been reported.

CHAPTER 81

# Treatment of Systemic Lupus Erythematosus

George Bertsias • Antonis Fanouriakis • Dimitrios T. Boumpas

**KEY POINTS**

- The treatment goal in systemic lupus erythematosus (SLE) is remission with a decrease in organ damage.
- Drug toxicity, especially from glucocorticoids, should be carefully considered and minimized as much as possible.
- Hydroxychloroquine (HCQ) maintenance is recommended for all patients with SLE who do not have contraindications to the use of this agent.
- SLE with severe, major organ involvement is usually managed with high-dose glucocorticoids and pulses of intravenous cyclophosphamide (CYC).
- In moderately severe lupus nephritis (LN), mycophenolate mofetil (MMF) is effective and has a better toxicity profile than CYC.
- Either azathioprine (AZA) or MMF is recommended for maintenance of renal response in moderate to severe LN.
- Belimumab (anti-Blys mAb) may be useful when standard therapies have failed Rituximab (anti-CD20 mAb) has been used by some clinicians in refractory cases.
- Family counseling and planning are important elements for the successful completion of pregnancies in women with SLE.

## GENERAL TREATMENT STRATEGY

**KEY POINTS**

- Treatment of moderate or severe systemic lupus erythematosus (SLE) requires induction immunosuppressive therapy followed by less intense maintenance therapy.
- Patients with SLE experience poor quality of life.
- Patients favor an active and collaborative role in decision making.

Systemic lupus erythematosus (SLE) activity usually follows the flare pattern, which is characterized by a relapsing-remitting course. However, an equal number of patients have continuously active disease, and only a few have long periods of disease quiescence.[1,2] Despite improvements in overall survival (85% to 90% during the first 10 years), some patients with SLE are still at risk for premature death.[3] Persistent inflammation inevitably results in irreversible major organ damage, which is linked to decreased quality of life and increased mortality.[4,5] Accordingly, therapeutic strategies should aim at reducing overall burden of systemic inflammation. Achieving these goals requires (1) accurate assessment of disease activity and flares, (2) stratification of patients according to severity of target organ involvement, (3) use of safe and effective drugs to induce remission promptly and prevent flares, and (4) prevention and management of disease and treatment-related comorbidities.[6]

In general, patients with mild lupus manifestations (skin, joint, and mucosal involvement) are treated with anti-malarials or disease-modifying anti-rheumatic drugs (DMARDs), alone or in combination with low-dose oral glucocorticoids (GCs). Severe SLE with major organ involvement requires an initial period of intensive immunosuppressive therapy (induction therapy) to control aberrant immunologic activity and halt tissue injury, followed by a longer period of less intensive and less toxic maintenance therapy, to consolidate remission and prevent flares. Immunosuppressive therapy helps reduce the use of GC, thus reducing their deleterious effects.

Patients with SLE experience poor quality of life, which is only in part associated with disease activity and organ damage. Important contributors include fatigue, fibromyalgia, depression, and cognitive dysfunction.[7,8] Treating physicians should regularly address these issues and engage symptomatic or remedial therapies as indicated. The realization that a significant proportion of patients have disease- and treatment-related comorbidities has shifted the attention of physicians to adjunct therapies and primary prevention strategies such as renoprotective and cardiovascular disease risk reduction measures.

Health professionals are increasingly encouraged to involve patients in treatment decisions, recognizing them as experts with a unique knowledge of their own health and their preferences for treatments, health states, and outcomes.[9] This approach may be particularly challenging in patients with severe lupus, who might benefit from cytotoxic therapy which is associated with significant toxicity.[10] Therefore, physicians should provide patients with balanced information to ensure accurate perception of the risks and benefits of prescribed medications.[11]

## DRUGS USED TO TREAT SYSTEMIC LUPUS ERYTHEMATOSUS

**KEY POINTS**

- The prescribed doses of GCs for long-term use should be as low as possible with the goal of no more than the prednisone equivalent of 7.5 mg/day.

**Anti-malarials are recommended for all patients with SLE because of their effectiveness in achieving remission in severe lupus and in reducing the risk of flare-ups and of damage accrual.**

**AZA is effective in mild to moderate SLE, including LN.**

**High-dose GCs with pulses of intravenous CYC are recommended for severe SLE with major organ involvement.**

**MMF is equally effective and has a better toxicity profile than CYC in moderately severe proliferative LN (PLN).**

**Calcineurin inhibitors can be used in refractory LN.**

**Belimumab is approved for active patients with SLE who are receiving standard therapy.**

**Rituximab has been used by some clinicians in cases refractory to immunosuppressive treatment.**

**Novel biologic therapies are currently being tested in SLE.**

## Glucocorticoids

GCs exert broad inhibitory effects on immune responses mediated by T and B cells, as well as on the effector functions of monocytes and neutrophils. On the basis of these effects and their rapid onset of action, GCs have been remarkably efficacious in managing acute SLE manifestations.

Low-dose GC therapy (≤7.5 mg prednisone equivalent per day) is generally used when other initial therapies (anti-malarials) are not tolerated or are inadequate to control disease activity. In moderate to severe disease, GCs are used as either single or background therapy in combination with immunosuppressive agents, at doses of 0.5 to 1 mg/kg prednisone equivalent in a single dose, usually in the morning. When combined with immunosuppressive agents, the GC dose should rarely exceed 0.5 to 0.6 mg/kg prednisone due to concerns for infections and other toxicities. Tapering of GC dose starts after the first 4 to 6 weeks of therapy, targeting a dose of 0.125 to 0.25 mg/kg given daily or every other day at 2 to 3 months. Concomitant use of immunosuppressive agents facilitates tapering and decreases cumulative GC toxicity.

Although two controlled studies[12,13] have suggested that short-term GC therapy (30 mg for 2 weeks, then quick tapering) reduces the risk of severe flare in patients with clinically stable but serologically active SLE, this practice may result in overtreating patients with higher cumulative GC doses. For these patients, vigilant monitoring for objective signs of disease exacerbation is recommended.

In severe, rapidly progressing disease or when doses greater than 0.6 mg/kg/day prednisone equivalent are required to control disease activity, GC pulse therapy may be introduced.[14,15] Intravenous (IV) pulses of methylprednisolone (MP) (500 to 1000 mg daily for 1 to 3 consecutive days) are used, although there is no strong evidence to support a survival advantage. In addition to expediting remission, IV MP pulses may allow for the use of lower GC doses during the induction period.

GC toxicity may involve early (mood effects, acne, myalgias, infections), later (metabolic), and late-onset (osteoporosis, avascular bone necrosis, cataract, cardiovascular disease) adverse events.[16] Although confounded by increased systemic disease activity, most effects are considered to be dependent on the cumulative dose and duration and, to a lesser extent, route of administration. Chronic exposure to GC doses higher than 6 to 7.5 mg/day of prednisone equivalent is clearly associated with an increased risk for irreversible organ damage.[17,18] Tailoring GC use on the basis of individual patient profile (disease activity, risk for toxicity) and prompt initiation of primary prevention measures (osteoporotic prophylaxis) is of paramount importance.

## Anti-malarials and DMARD Therapy

### Hydroxychloroquine

Anti-malarial drugs, mainly chloroquine and hydroxychloroquine (HCQ), are commonly prescribed to patients with SLE with skin and joint manifestations but are increasingly identified as an adjuvant treatment for achieving remission in severe lupus. Use of anti-malarials resulted in a greater than 50% reduction in SLE disease activity of all types and to a moderate reduction in severe flares and GC dose.[19] In a randomized controlled trial (RCT) in stable active patients with SLE on HCQ treatment, those who achieved blood HCQ levels greater than or equal to 1000 ng/mL had a tendency for reduced SLE flares (20.5% vs. 35.1%) during a 7-month period.[20] Beneficial effects on the lipid profile and subclinical atherosclerosis markers have also been described.[21] Importantly, prospective observational studies have reported an inverse association between use of HCQ and accrual of irreversible organ damage.[4,19] Although these findings may be confounded by milder forms of disease usually present in patients with SLE who are prescribed anti-malarials, the presumptive mode of the action of anti-malarials by inhibition of innate immunity pathways provides a plausible explanation for their multifold beneficial effects.[22] Furthermore, the use of HCQ has been associated with a decreased incidence of diabetes[23] and improved outcomes in patients with anti-phospholipid antibodies/anti-phospholipid syndrome (APS).[24,25] HCQ is well tolerated, with low rates of mild gastrointestinal and skin adverse events. Retinal toxicity is uncommon (estimated at 0.1% in patients who received HCQ for more than 10 years[19]), but routine ophthalmologic evaluation is recommended (annual screening during the first 5 years of usage is recommended for individuals who are treated with high HCQ doses (>6.5 mg/kg), for those treated more than 5 years, or for those who have other complicating factors).[26]

### Methotrexate

Methotrexate (MTX) has been used as a steroid-sparing treatment in mild to moderate SLE, particularly for articular and cutaneous manifestations of SLE.[27,28] MTX is administered once weekly either orally or parenterally. A systematic literature review reported significant reduction of the SLE Disease Activity Index (SLEDAI) among MTX-treated patients when compared with controls (odds ratio [OR], 0.44), followed by significant reduction in the average dose of corticosteroids (OR, 0.34).[29] Concomitant administration of folic acid (1 to 2 mg/day, is recommended to minimize toxicity (Table 81-1; see also Chapter 61).

**TABLE 81-1** Recommended Therapeutic Drug Monitoring in Systemic Lupus Erythematosus

| Drug | Dosage | Dose Adjustment | Toxicities Requiring Monitoring | Baseline Evaluation | Laboratory Monitoring |
|---|---|---|---|---|---|
| Azathioprine | 50-200 mg/day in 1-3 doses with food | ↓ 25% if eGFR 10-30 mL/min; ↓ 50% if eGFR < 10 mL/min | Myelosuppression, hepatotoxicity, lymphoproliferative diseases | CBC, platelets, Cr, AST or ALT | CBC and platelets every 2 wk, with changes in dosage; baseline tests every 1-3 mo |
| Mycophenolate mofetil | 1-3 g/day in 2 divided doses with food | Maximum 1 g/day if eGFR < 25 mL/min | Myelosuppression, hematotoxicity, infection | CBC, platelet, Cr, AST or ALT | CBCs and platelets every 1-2 wk with changes in dosage; baseline tests every 1-3 mo |
| Cyclophosphamide | 50-150 mg/day in a single dose with breakfast. Increase fluid intake (at least 3 L water/day), empty bladder before bedtime* | ↓ 25% if eGFR 25-50 mL/min; ↓ 30%-50% if eGFR < 25 mL/min; ↓ 25% if serum Bil 3.1-5 mg/dL or transaminases >3 times ULN | Myelosuppression, hemorrhagic cystitis, myeloproliferative disease, malignancies | CBC, platelet, Cr, AST or ALT, urinalysis | CBC with differential every 1-2 wk, with changes in dosage and then every 1-3 mo; keep WBC > 4000/mm$^3$ with dose adjustment; urinalysis, AST or ALT every 3 mo; urinalysis every 6-12 mo following cessation |
| Methotrexate | 7.5-25 mg/wk in 1-3 doses with food or milk/water | ↓ 50% if eGFR 10-50 mL/min; avoid use if eGFR < 10 mL/min; avoid use in hepatic dysfunction (serum Bil 3.1-5 mg/dL or transaminases >3 times ULN) | Myelosuppression, hepatic fibrosis, pneumonitis | CXR, hepatitis B/C serology in high-risk patients, AST or ALT, Alb, ALP, Cr | CBC with platelet, AST, Alb, Cr every 1-3 mo |
| Cyclosporin A | 100-400 mg/day in 2 doses at the same time every day with meal or between meals | Avoid in impaired renal function | Renal insufficiency, anemia, hypertension | CBC, Cr, uric acid, AST or ALT, Alb, ALP, blood pressure | Cr every 2 wk until dose is stable, then monthly; CBC, potassium, AST or ALT, Alb, and ALP every 1-3 mo; drug levels only with doses >3 mg/kg/day |
| Tacrolimus | 1-4 mg/day in 2 doses at the same time every day | Cautious use in liver or renal insufficiency | Renal insufficiency, neurotoxicity, malignancy, infections, hyperkalemia | Cr, potassium, AST or ALT, glucose, blood pressure | Baseline tests once a week for the first 3-4 wk, then every 1-3 mo; monitor drug trough levels |
| Leflunomide | 100 mg/day in a single dose for 3 days, then 10-20 mg/day | Avoid in hepatic dysfunction (serum Bil 3.1-5 mg/dL or transaminases >3 times ULN) | Myelosuppression, hepatotoxicity, fetal toxicity | CBC, Cr, AST or ALT, Alb, ALP | CBC, AST or ALT, Alb, and ALP monthly for 6 mo, then every 1-3 mo; monthly monitoring if MTX coadministered |
| Rituximab† | 1000 mg on day 1 and 15 | None | HBV reactivation (rare) | CBC, Cr, AST or ALT, HBV serology (high-risk patients), TST | CBC and platelets |

*See Table 81-3 for IV dosing for Cyclophosphamide.

†Note that placebo controlled studies have failed to demonstrate efficacy in controlled clinical trials.

Alb, Serum albumin; ALP, alkaline phosphatase; ALT, alanine transaminase; AST, aspartate transaminase; Bil, bilirubin; CBC, complete blood cell count; Cr, serum creatinine; CXR, chest x-ray; eGFR, estimated glomerular filtration rate; HBV, hepatitis B; LFTs, liver function tests; MTX, methotrexate; TST, tuberculin skin testing; ULN, upper limit of normal; WBC, white blood cell count.

### Leflunomide

Leflunomide has been used in patients with SLE with mild to moderate disease activity, as well as in lupus nephritis (LN) refractory or intolerant to standard immunosuppressive therapy.[30,31] The drug has an elimination half-life of 14 to 18 days and is contraindicated in patients who are trying to become or are pregnant because of its teratogenicity (see also Chapter 61). As a result of this long half-life, if a patient has ever taken leflunomide, she should have leflunomide levels checked before conception.

## Cytotoxic Therapy

### Cyclophosphamide

**Pharmacology and Route of Administration.** Cyclophosphamide (CYC) is an alkylating agent that depletes lymphocytes and reduces the production of autoantibodies in lupus (Table 81-2). Both oral and IV administration of CYC result in similar plasma concentrations, and the serum half-life is approximately 6 hours. CYC is metabolized to various active metabolites by cytochrome P450 in the liver or other

**TABLE 81-2** Indications for Immunosuppressive Therapy in Systemic Lupus Erythematosus

| |
|---|
| **General Indications** |
| Involvement of major organs or extensive involvement of nonmajor organs (skin) refractory to other agents, or both |
| Failure to respond to or inability to taper corticosteroids to acceptable doses for long-term use |
| **Specific Organ Involvement** |
| **Renal** |
| Proliferative or membranous nephritis (nephritic or nephritic syndrome), or both |
| **Hematologic** |
| Severe thrombocytopenia (platelets <20,000/mm$^3$) |
| Thrombotic thrombocytopenic purpura-like syndrome |
| Severe hemolytic or aplastic anemia, or immune neutropenia not responding to glucocorticoids |
| **Pulmonary** |
| Lupus pneumonitis or alveolar hemorrhage, or both |
| **Cardiac** |
| Myocarditis with depressed left ventricular function, pericarditis with impending tamponade |
| **Gastrointestinal** |
| Abdominal vasculitis |
| **Nervous System** |
| Transverse myelitis, cerebritis, optic neuritis, psychosis refractory to corticosteroids, mononeuritis multiplex, severe peripheral neuropathy |

tissues. Drugs that induce hepatic microsomal enzymes (barbiturates, alcohol, phenytoin, rifampin) may accelerate the metabolism of CYC into its active metabolites and thus increase its pharmacologic and toxic effects. Conversely, drugs that inhibit the hepatic microsomal enzymes (antimalarials, tricyclic anti-depressants, and allopurinol) may slow the conversion of CYC to active metabolites. Approximately 20% of the drug is excreted by the kidneys, and dose modification is necessary for patients with renal impairment.

The National Institutes of Health (NIH) trials demonstrated equivalent efficacy yet lower toxicity with monthly IV (0.5 to 1 g/m$^2$) versus oral regimens, which led to the predominant use of IV CYC in clinical practice (Table 81-3). Reversible myelotoxicity is common and dose related. After pulse therapy, the nadir of the patient's lymphocyte count occurs on days 7 to 10 and that of granulocyte count on days 10 to 14. The dose should be adjusted to keep the patient's white blood cell count higher than 3000 cells/mm$^3$. A prompt recovery from granulocytopenia usually occurs after 21 to 28 days. Thrombocytopenia is rare in CYC monotherapy. Reversible alopecia and nausea are common, whereas infections (especially herpes zoster), gonadal toxicity, and malignancy (including bladder toxicity and carcinoma) are less frequent although much more serious adverse

**TABLE 81-3** National Institutes of Health Protocol for Administration and Monitoring of Pulse Intravenous Cyclophosphamide Therapy

| |
|---|
| Estimate GFR by standard methods (Cockcroft-Gault or the Modification of Diet in Renal Disease formula) |
| Calculate body surface area (m$^2$): BSA = ✓ Height (cm) × Weight (kg)/3600 |
| Cyclophosphamide (Cytoxan) (CYC) dosing and administration:<br>Initial dose 0.75 g/m$^2$ (0.5 g/m$^2$ if GFR less than one-third of expected normal)<br>Administer CYC in 150 mL normal saline IV during 30-60 min (alternative: equivalent dose of pulse CYC may be taken orally in highly motivated and compliant patients)<br>Determine WBC at days 10 and 14 after each CYC pulse (patient should delay prednisone until after blood tests drawn to avoid transient steroid-induced leukocytosis)<br>Adjust subsequent doses of CYC to maximum dose of 1 g/m$^2$ to keep nadir WBC >1500/mm$^3$. If WBC nadir falls <1500/mm$^3$, decrease next dose by 25% |
| Repeat IV CYC pulses monthly (every 3 wk in extremely aggressive disease) for another 6 mo (total 7 pulses), then quarterly for 1 year after remission is achieved (inactive urine sediment, proteinuria <1 g/day, normalization of complement [and ideally anti-dsDNA], and minimal or no extrarenal lupus activity) |
| Protection of urine bladder against CYC-induced hemorrhagic cystitis<br>Diuresis with 5% dextrose and 0.45% saline (2 L at 250 mL/hr). Frequent voiding; continue high-dose oral fluids for 24 hr. Patients return to clinic if they cannot sustain an adequate fluid intake<br>Consider mesna (each dose 20% of total CYC dose) intravenously or orally at 0, 2, 4, and 6 hr after CYC dosing. Mesna is especially important to use when sustained diuresis may be difficult to achieve or if pulse CYC is administered in an outpatient setting<br>If anticipating difficulty with sustaining diuresis (e.g., severe nephrotic syndrome) or with voiding (e.g., neurogenic bladder), insert a 3-way urinary catheter with continuous bladder flushing with standard antibiotic irrigating solution (e.g., 3 L) or normal saline for 24 hr to minimize risk of hemorrhagic cystitis |
| Antiemetics (usually administered orally)<br>Dexamethasone (10 mg single dose) *plus*<br>Serotonin receptor antagonists: granisetron 1 mg with CYC dose (usually repeat dose in 12 hr); ondansetron 8 mg three times daily for 1-2 days |
| Monitor fluid balance during hydration. Use diuresis if patient develops progressive fluid accumulation |
| Complications of pulse CYC<br>Expected: nausea and vomiting (central effect of CYC) mostly controlled by serotonin receptor antagonists; transient hair thinning (rarely severe at CYC doses ≤1 g/m$^2$)<br>Common: significant infection diathesis only if leukopenia not carefully controlled; modest increase in herpes zoster (very low risk of dissemination); infertility (male and female); amenorrhea proportional to age of the patient during treatment and to the cumulative dose of CYC. In females at high risk for persistent amenorrhea, consider using leuprolide, 3.75 mg, subcutaneously 2 wk before each dose of CYC |

CYC, Cyclophosphamide; GFR, glomerular filtration rate; IV, intravenous; WBC, white blood cell count.

events (see Comorbidities in Systemic Lupus Erythematosus and Women's Health Issues later in the text).

**Use in Lupus Nephritis.** RCTs with long-term follow-up have shown that intermittent pulse IV CYC therapy is effective for moderate to severe proliferative lupus nephritis (PLN).[32, 33] CYC may retard progressive renal scarring, preserve renal function, and reduce the risk for the development of end-stage renal disease (ESRD).[34] Following induction therapy, a maintenance regimen is necessary to decrease the risk of flares.[35] A combination of pulse therapy with IV CYC and IV MP improves renal outcomes without increasing toxicity.[36,37] The authors propose that severe PLN (with acute reduction in glomerular filtration rate [GFR] and/or adverse renal biopsy findings) should be treated with 7 monthly pulses of IV CYC (0.5 to 1 g/m$^2$), followed by quarterly pulses for at least 1 year after remission. In most severe cases, monthly pulses of IV MP may be given during the induction period.

In the Euro-Lupus Nephritis Trial that studied white patients with milder forms of LN, low-dose IV CYC (6 fortnightly pulses at a fixed dose of 500 mg each in combination with three daily doses of 750 mg of IV MP), followed by azathioprine (AZA) for maintenance had comparable efficacy and less toxicity than high-dose IV CYC (8 pulses).[38] Mean patient survival rate at 10 years was 92% for both groups; ESRD and doubling of Cr rates did not differ between the two groups.[33] Therefore, low-dose IV CYC may be an alternative option for white patients with moderately severe LN. The regimen has also been used in nonwhite patients but further studies will be required to determine its efficacy.[39]

Austin and colleagues[40] compared cyclosporin A (CsA), IV CYC (0.5 to 1 g/m$^2$ × 6 bimonthly doses), and GC alone in 42 patients with lupus membranous nephropathy (LMN). All patients received alternate-day oral prednisone (1 mg/kg every other day for 8 weeks, then tapered). At 1 year, the cumulative probability of remission was 27% with prednisone, 60% with IV CYC, and 83% with CsA. Rates of nephrotic syndrome relapse were 10 times higher in patients treated with CsA versus those treated with IV CYC. Thus, although IV CYC and CsA are equally effective as induction therapy in LMN, patients treated with CsA may require maintenance therapy (with lower doses of CsA, or AZA, or MMF) to prevent relapses.

**Use in Extrarenal Disease.** CYC has demonstrated efficacy in life-threatening or refractory extrarenal lupus manifestations such as severe thrombocytopenia (platelet count <20,000/mm$^3$), neurologic disease, abdominal vasculitis, acute pneumonitis/alveolar hemorrhage, and extensive skin disease.[41,42] Barile-Fabris and colleagues[43] have reported the superiority of IV CYC versus IV MP for severe nonthrombotic neurologic SLE (seizures, peripheral neuropathy, optic neuritis, transverse myelitis, brain stem disease, coma, internuclear ophthalmoplegia).

## Anti-metabolites

### Azathioprine

AZA inhibits the conversion of purine bases such as inosine to adenine and guanine ribonucleotides. AZA (2 to 2.5 mg/kg/day) is safe in the long term with no significant increase in the risk for infection, whereas it is associated with a marginally increased risk for malignancy. Gastrointestinal complaints are frequent and cause 15% to 30% of patients to discontinue the drug within 6 months. Mild liver enzyme elevation may occur, but severe liver injury is rare. Reversible, dose-related bone marrow toxicity is also common; leukopenia is encountered in 4.5% and thrombocytopenia in 2% (see Table 81-1) of patients, respectively. AZA toxicity has been associated with genetic polymorphisms resulting in decreased thiopurine methyltransferase (TPMT) activity and impaired ability to detoxify intermediate metabolites.[44] Genetic testing is available for *TPMT* variant alleles so that the starting dosages of AZA can be adjusted accordingly (see also Chapter 62). Concomitant use of allopurinol, which inhibits xanthine oxidase (the enzyme that metabolizes AZA) substantially increases toxicity and should be avoided.

Patients with manifestations such as mild PLN, thrombocytopenia with platelet count in the range of 20 to 50 × 10$^3$/mm$^3$, and serositis may respond to AZA, usually in combination with moderate to high GC doses (see Table 81-2). In a controlled study, European patients with PLN were randomly assigned to receive pulse IV CYC plus prednisone versus IV MP plus AZA plus a tapering dose of prednisone.[27] Both groups received maintenance therapy with AZA plus prednisone after the second year. After a median follow-up of 9.6 years, there were no significant differences between the two groups in rates of sustained doubling of Cr, ESRD, or mortality.[45] However, renal relapses occurred more often in the AZA group (hazard risk [HR], 4.5). Repeat renal biopsies showed that progression of chronic lesions was more effectively halted by CYC than by AZA.[46] Thus AZA should be used only in mild LN or in patients strongly opposed to or who cannot tolerate CYC or MMF. AZA has also been used in combination with GC in pure LMN, although approximately one out of three patients may experience relapse during follow-up.[47]

AZA is efficacious for maintenance of response in SLE.[33,48,49] Two RCTs have compared AZA versus MMF as maintenance regimens in PLN. In the MAINTAIN trial, which included European patients who received induction with low-dose IV CYC, both agents were equally efficacious in terms of time-to-renal flare, severe flares, renal remission, and doubling of Cr.[50] Repeat kidney biopsies failed to reveal histologic differences between the two groups.[51] In contrast, the Aspreva Lupus Management Study (ALMS), which included a larger number of patients with multiethnic backgrounds who were induced with either IV CYC or MMF, reported increased renal flares in the AZA versus the MMF group (see mycophenolate mofetil in the next section).[52] To this end, both agents can be used as maintenance therapy[53] on the basis of availability, clinical experience, and potential for pregnancy, because MMF is associated with an increased risk of spontaneous abortion and fetal malformation.

### Mycophenolate Mofetil

**Pharmacology.** Mycophenolate is a prodrug of mycophenolic acid (MPA), a potent inhibitor of inosine monophosphate dehydrogenase that is indispensable for the de novo synthesis of guanosine nucleotides. It is orally administered

either as mycophenolate mofetil (MMF) or as enteric-coated mycophenolate sodium (eMPA). A 720 mg dose of eMPA is roughly equivalent to a 1 g dose of MMF. The lack of any salvage nucleotide synthesis pathway in lymphocytes renders them a selective target for MMF. MMF has excellent oral bioavailability, with peak levels occurring within 1 to 2 hours after administration, and a half-life of 17 hours. Although therapeutic drug monitoring to guide MMF dosing has been proposed in renal transplantation, validation of therapeutic MPA monitoring in LN is still required.[54] Antacids and cholestyramine decrease the bioavailability of MMF, and coadministration with AZA should be avoided. MMF is teratogenic and should not be administered during pregnancy.

**Use in Lupus Nephritis.**

Induction Therapy. Several RCTs have demonstrated equal or even superior efficacy of MMF versus CYC in inducing renal response in PLN. The ALMS, one of the largest and most racially diverse RCT in LN, failed to demonstrate the superiority of MMF (2 to 3 g/day) versus monthly pulses of IV CYC (0.5 to 1 g/m$^2$), both combined with oral prednisone (maximum starting dose, 60 mg/day).[55] At 6 months, response rates were 56% for patients treated with MMF and 53% for patients treated with IV CYC. Post-hoc analysis suggested superiority of MMF in black and Hispanic patients.[56] Meta-analyses of the previously mentioned and other RCTs have concluded that MMF is as effective as CYC for induction treatment of PLN and is associated with lower risks of leukopenia, amenorrhea, and alopecia.[57,58] MMF may therefore be considered as first-line treatment in moderately severe PLN, especially when gonadal toxicity is an issue.

Preliminary evidence suggests that MMF is efficacious in severe forms of PLN, such as with impaired renal function or with crescents in renal glomeruli.[59,60] However, further studies with long-term follow-up are needed to determine whether MMF is equally effective as CYC in averting ESRD in LN.[61]

A pooled analysis of 84 patients with pure LMN who participated in two RCTs has demonstrated comparable anti-proteinuric effects and nephrotic syndrome remission rates in MMF- and IV CYC–treated patients.[62] Consequently, and based on its more favorable toxicity profile compared with CYC, MMF is considered as first-line treatment of LMN.

Maintenance Therapy. Meta-analysis of RCTs comparing MMF versus AZA as maintenance therapy in PLN[48,50,52] showed comparable rates of renal remission, doubling of Cr, and renal remission during a 3-year period.[53] However, treatment with AZA was associated with increased risk for renal relapses (relative risk [RR] 1.45) and leukopenia (RR, 7.1). To this end, both MMF and AZA can be used for maintenance of response in PLN on the basis of availability and potential for pregnancy. Early (before 18 to 24 months) discontinuation of MMF or switching to other immunosuppressant is associated with increased risk for renal flare.[63]

**Use in Extrarenal Lupus.** MMF has been successful in cases of refractory skin and blood manifestations in SLE.[64] Post-hoc analysis of the ALMS data showed that MMF was equally efficacious with IV CYC pulse therapy on controlling extrarenal disease activity, particularly in the general, mucocutaneous, musculoskeletal, and hematologic domains.[65] While awaiting additional data to define the efficacy of MMF in extrarenal lupus, the drug may be used in patients with moderately severe lupus who are intolerant or have not adequately responded to AZA.

## Calcineurin Inhibitors

### Cyclosporin A

**Pharmacology.** CsA, a fungus-derived calcineurin inhibitor that deactivates T cells, also reduces antigen presentation and autoantibody production by lupus B cells. Following oral administration, peak serum concentration occurs within 1 to 8 hours. Drug concentration is measured in whole blood, but this is rarely necessary in autoimmune diseases, unless CsA is used in doses greater than or equal to 3 mg/kg/day. Clinical response occurs 1 to 2 months after treatment initiation. Numerous drugs interact with CsA, leading to reduced drug concentrations (rifampin, phenytoin, phenobarbital, nafcillin) or increased CsA concentrations (erythromycin, clarithromycin, azoles, calcium channel blockers, amiodarone, allopurinol, colchicine). Other drugs may augment CsA's nephrotoxic effects (NSAIDs, aminoglycosides, quinolones, angiotensin-converting enzyme [ACE] inhibitors, amphotericin B). Common adverse effects include gastrointestinal complaints, hirsutism, gingival hyperplasia, and mild elevation in serum alkaline phosphatase levels. Tremor, paresthesias, electrolyte disturbances (hyperkalemia and hypomagnesemia), and hyperuricemia may also occur. Hypertension occurs in nearly 20% of patients receiving CsA and is controlled by either reduction of the dose or anti-hypertensive treatment. A significant adverse effect is nephrotoxicity, which is reversible after adjustment of the dose or drug discontinuation. Physicians should avoid use of CsA in patients with impaired renal function (see Table 81-1).

**Use in Proliferative Lupus Nephritis.** CsA, used in combination with GC, has demonstrated efficacy in PLN, including refractory cases.[66] In the CYCLOFA-LUNE trial, 40 patients with newly diagnosed PLN and mild renal insufficiency received sequential induction-maintenance therapy with either CYC (oral boluses 10 mg/kg) or CsA (4 to 5 mg/kg/day, then tapered), both combined with oral GC.[67] At 9 months, 76% of the CYC group and 68% of the CsA group achieved renal response, and after median follow-up of 7.7 years, the two groups had comparable rates of ESRD, adverse events, mean Cr, proteinuria, and Systemic Lupus International Collaborating Clinics (SLICC) damage score.[68] Moroni and colleagues[49] have also demonstrated comparable efficacy of AZA versus CsA as maintenance therapies in patients with diffuse PLN and preserved renal function. Together, CsA can be used for the induction and maintenance treatment of PLN, although it is not preferred as a first-line option because of its safety profile.

**Use in Membranous Lupus Nephropathy.** Balow and Austin[40] compared treatment with prednisone alone or in combination with CsA or pulses of IV CYC in the treatment of membranous lupus nephropathy (MLN). Remission rates at 1 year were 27% for prednisone, 60% for IV CYC, and 83% for CsA. After treatment discontinuation, however, rates of nephrotic syndrome relapse were 10-fold higher in the CsA than in the IV CYC group, suggesting

that, at a minimum, patients treated with CsA may require maintenance therapy to prevent relapses in MLN.

**Use in Extrarenal Lupus.** Uncontrolled studies of short duration have shown improvement in disease activity, anti-double-stranded (ds)DNA titers, and cytopenias, with modest GC reduction in patients with SLE who received low-dose CsA.[69,70] The British Isles Lupus Assessment Group (BILAG) group compared the steroid-sparing effect of CsA (2.5 to 3.5 mg/kg/day) versus AZA (2 to 2.5 mg/kg/day) in moderately severe lupus.[71] Although nearly 50% of the patients failed to respond, the mean reduction in prednisolone dose at 12 months was 9.5 mg in the CsA group and 10.2 mg in the AZA group. The two groups performed similarly with regard to disease activity, response to treatment, flares, damage accrual, and quality-of-life measures. Thus CsA may be used as an alternative steroid-sparing agent to AZA in patients with SLE but with close monitoring of the renal function and blood pressure.

### Tacrolimus

Tacrolimus (TAC) is a 10 to 100 times more potent calcineurin inhibitor than CsA. Dose-dependent reversible nephrotoxicity and blood pressure elevation have been reported, although less often than with CsA. Other adverse effects include cardiomyopathy in children, anxiety, seizures, delirium and tremor, diabetes, and hyperlipidemia. In patients with skin and musculoskeletal lupus, TAC (1 to 3 mg/day for 1 year) resulted in significant reduction in disease activity and the dose of GC.[72]

Controlled studies have demonstrated beneficial effects of TAC in PLN and MLN, including cases of refractory disease.[73] In Asian patients with LN with relatively preserved renal function, TAC exhibited fast anti-proteinuric action and at least equal efficacy with MMF or IV CYC in inducing renal response at 6 to 12 months.[74-76] In Chinese patients with class III-IV (81%) or pure class V (19%) LN, prednisolone (0.6 mg/kg/day) was administered with either TAC (0.06 to 0.1 mg/kg/day) or MMF (2 to 3 g/day).[77] At 6 months, complete renal response was achieved by 59% of patients in the MMF and 62% of patients in the TAC group. During maintenance with AZA, proteinuric and nephritic flares developed in 24% of patients and 18% of patients in the MMF group, and 35% and 27% in the TAC group, respectively.[77] Long-term maintenance treatment with TAC has also been used, although hypertension and/or metabolic adverse events may develop in a considerable proportion of patients.[78] Further studies in non-Asian patients are eagerly awaited.

TAC has been used in combination with MMF to treat severe or resistant LN.[79-81] A multicenter RCT in Chinese patients with new-onset active LN compared the combination of TAC (4 mg/day) and MMF (1.0 g/day) versus monthly pulses IV CYC (0.5 to 1.0 g/m$^2$) for 6 months. Both regimens were combined with GCs. Complete renal response rates were 46% with the MMF/TAC combination versus 26% with IV CYC.[82] These results need cautious interpretation because of the fast anti-proteinuric effect of TAC and the lack of long-term safety and efficacy data. Nonetheless, such "multitarget" treatment might represent an option for LN patients with incomplete response to standard immunosuppressive treatment.

## Biologic Therapies

### Belimumab

The B lymphocyte stimulator protein (BLyS, also known as B cell activation factor [BAFF]) and the proliferation-inducing ligand (APRIL) are growth factors important for B cell survival and maturation. BLyS binds to three different B cell receptors, namely, the transmembrane activator and calcium-modulating cyclophilin ligand interactor (TACI), the B cell maturation antigen (BCMA), and the BAFF receptor, whereas APRIL signals through TACI and BCMA.[90]

Belimumab is a fully human anti-BLyS monoclonal antibody. Two phase III placebo-controlled RCTs (BLISS-52,[91] BLISS-76[92]) evaluated two different doses of belimumab (1 mg/kg, 10 mg/kg; dosed IV on days 0, 14, 28, and then every 28 days) on top of standard therapy in more than 1500 serologically positive (anti-nuclear antibody [ANA] ≥1:80 and/or anti-dsDNA ≥30 IU/mL) patients with SLE, using the composite SLE Responder Index (SRI) as the primary endpoint. Enrolled patients had moderately active SLE (average SLEDAI, 9.7), 57% had involvement of at least three different organs (excluding active severe renal or CNS lupus), and 25% were receiving treatment with GC plus anti-malarials plus one immunosuppressive agent (MTX, AZA, or MMF). Belimumab treatment resulted in a modest, although significant, reduction in disease activity (pooled results from the two RCTs: 50.6% in patients treated with 10 mg/kg belimumab vs. 30.8% in placebo met the study endpoint.).[93] Most improved were the musculoskeletal (arthritis), mucocutaneous (alopecia, ulcers, malar rash), and immunologic domains, and also skin vasculitis. Belimumab-treated patients exhibited significantly reduced risk for severe SLE flares (HR, 0.74), modest reductions in GC dose, and improvements in fatigue and health-related quality of life. Although patients with active severe LN were excluded from the trials, a significant anti-proteinuric effect was observed with belimumab.[94] Post-hoc analysis showed that drug effectiveness was higher in patients who had SLEDAI scores greater than or equal to 10 or serologic activity (low C3/C4 and/or high anti-dsDNA), or those who were on GCs upon enrollment.[95] Long-term follow-up data suggest that belimumab is generally well tolerated, with no significant increase in risk for serious infections, although infusion reactions can be encountered especially during the first three infusions.[96] These data opened the way for approval of this agent for the treatment of patients with active nonrenal/non-CNS SLE despite standard therapy (Table 81-4).

### Rituximab

Rituximab (RTX) is a chimeric mouse-human monoclonal antibody that targets the cell membrane protein CD20, which is expressed in all developmental stages of B cells, except for the hematopoietic stem cell and the plasma cell. Its mechanism of action involves cytotoxicity through complement activation, antibody-dependent cell-mediated cytotoxicity, and induction of apoptosis. RTX is well tolerated, with mild infusion reactions the most common adverse event. These reactions are usually prevented by premedication with antihistamines and GCs. Mild infections

**TABLE 81-4** Candidate Patients for Treatment with Belimumab

| |
|---|
| Active SLE (SLEDAI ≥8) in spite of standard-of-care therapy, including GCs, anti-malarials, and/or DMARDs/immunosuppressives |
| Higher efficacy in patients with SLEDAI ≥10 or with concomitant serologic activity (high anti-dsDNA and/or low serum C3/C4) |
| Conventional treatment should have been uptitrated as tolerated |
| Belimumab is not indicated for the management of active LN or NPSLE |
| High risk for disease flares |
| Young-onset disease (≤25 years old); persistent disease activity, history of renal, CNS involvement, or skin vasculitis; organ damage (SDI >0); serologic activity, previous SLE flares, no treatment with anti-malarials |
| Failure to taper GC to <7.5 mg/day prednisone equivalent |
| Intolerance to DMARDs/immunosuppressives |

GC, Glucocorticoid, CNS, central nervous system, DMARDs, disease-modifying anti-rheumatic drugs; LN, lupus nephritis; NPLSE; neuropsychiatric systemic lupus erythematosus.; SLE, system lupus erythematosus; SLEDAI, SLE Disease Activity Index.

are common (occurring in as many as 20% of patients), but the overall risk for serious or opportunistic infections is not significantly increased. Following the report of a few cases of progressive multifocal leukoencephalopathy (PML) in RTX-treated patients with rheumatoid arthritis (RA) and SLE, the U.S. Food and Drug Administration (FDA) has issued an alert about this association. While open label studies suggest efficacy in lupus, controlled clinical trials have so far failed to show statistically significant clinical benefit.

**Use in Extrarenal Lupus.** In the Exploratory Phase II/III SLE Evaluation of Rituximab (EXPLORER) trial, patients with active moderate to severe extrarenal SLE were randomly assigned to receive RTX (two biweekly infusions of 1000 mg at baseline and at 6 months) or placebo, in combination with background immunosuppression (AZA, MMF, MTX) and prednisone (0.5 to 1 mg/kg/day).[83] At week 52, no difference was observed between patients treated with RTX and placebo in major or partial clinical responses. However, high background therapies could have masked RTX effects. Conversely, evidence from several uncontrolled studies, including more than 1200 patients with SLE with refractory-to-immunosuppressive therapy nonrenal manifestations, suggests the efficacy of RTX, which is mainly used as add-on therapy to GCs, other immunosuppressive agents, or both.[84] Complete or partial responses were noted in 64% to 91% of patients within 3 to 9 months, particularly in the musculoskeletal (arthritis), hematology (autoimmune hemolytic anemia, thrombocytopenia) and immunology domains. Relapses occurred in 25% to 85% of patients after 3 to 18 months, and most appeared to be successfully re-treated with RTX in these observational reports.[84]

**Use in Lupus Nephritis.** The LUNAR trial evaluated RTX versus placebo, both in combination with MMF (3 g/day), in 144 patients with active PLN.[85] By week 52, there was no significant difference between the two groups in terms of renal response. Similar to the EXPLORER trial, high background treatment with MMF could have masked RTX superiority versus placebo. In contrast, observational data from 300 patients with active LN, in spite of treatment with GCs plus immunosuppressives (CYC, MMF, or AZA), supports RTX efficacy.[86] After an average of 60 weeks, rates of complete and partial renal response were approximately 40% and 34%, respectively, with lower responses in mixed class V + III-IV or pure class V LN. In a nonrandomized study, patients with active PLN received induction treatment with GCs plus either RTX (1000 mg on days 0 and 14), or MMF (2 to 2.5 g/day) or low-dose IV CYC (3 g), followed by maintenance with AZA, MMF, or CsA.[87] Renal response rates at 12 months were comparable between the RTX, MMF, and IV CYC groups (71%, 53%, and 65%, respectively). The same group treated PLN patients seen with severe proteinuric flare with oral CYC (1 to 2 mg/kg/day for 3 months) or RTX, followed by maintenance with MMF or AZA.[88] At 3 months, resolution of proteinuria (<0.5 g/24 hr) occurred in 20% of RTX-treated versus 7% of CYC-treated patients. At 12 months, the respective figures were 90% versus 71%.[88] Although the previously mentioned studies are small and nonrandomized, they provide further evidence for the efficacy of RTX in the treatment of refractory/relapsing LN. Efforts to combine RTX, MMF, and pulses of IV MP with no oral GCs as induction treatment of LN are currently under investigation.[89]

## Biologic Therapies Under Development

### Ocrelizumab

The BELONG trial evaluated ocrelizumab (humanized anti-CD20 monoclonal antibody) versus placebo, both in combination with either MMF (as much as 3 g/day) or IV CYC (Euro-Lupus protocol) in PLN.[97] The study was prematurely terminated because of increased rates of serious infections in ocrelizumab-treated patients.

### Epratuzumab

Epratuzumab is a recombinant anti-CD22 monoclonal antibody that modulates B cell function.[81] Positive results were announced for phase IIb trials in moderate to severe SLE.[98,99] Patients who received epratuzumab 2400 mg cumulative dose had significant improvements in disease activity compared with placebo. Incidence of serious adverse events and infusion reactions was similar between the epratuzumab and placebo groups.[99]

### Atacicept

Atacicept (TACI-Ig) is a recombinant fusion protein of the extra-cellular domain of TACI and the human IgG1.Fc domain. TACI mediates signals from both BLyS and APRIL, thus affecting memory B cells, plasma cells, and immunoglobulin production. Two phase II/III RCTs of atacicept in LN (administered in combination with MMF)[100] and in moderately severe SLE,[101] were prematurely terminated because of cases of fatal infections.

### Blisibimod

Blisibimod selectively inhibits both soluble BAFF and membrane-bound BAFF. In active patients with SLE with

positive ANA and/or anti-dsDNA antibodies, blisibimod, 200 mg once-weekly, demonstrated efficacy versus placebo,[102] with reductions in flares, dose of GCs, proteinuria levels, and improvements in serology. The drug was generally well tolerated, with the exception of some injection site reactions. Further studies will be required to further define its efficacy and safety in SLE.

### Abatacept

Abatacept (CTLA4-Ig) antagonizes CD28-mediated T cell activation and is currently approved for the treatment of RA and juvenile idiopathic arthritis. A phase IIb trial of abatacept in combination with GC and background immunosuppressive therapy in patients with SLE failed to meet its primary endpoint (prevention of flares).[103] Two RCTs have evaluated abatacept in combination with MMF[104] or low-dose IV CYC[39] as induction treatment of PLN. The results of both trials were negative, although data reanalysis by using alternative renal response criteria suggested the superiority of abatacept versus placebo.[105] Further studies will be required to define the usefulness of the drug in LN.

### Interferon Inhibition

Type I interferon (IFN-α) has been implicated in lupus pathogenesis through breakdown of immune tolerance. Two phase IIb trials targeting IFN-α with sifalimumab (anti–IFN-α mAb) or anifrolumab (anti–IFN-α receptor subunit 1 mAb) yielded encouraging results. In patients with seropositive moderate to severe SLE, despite standard-of-care treatment, sifalimumab treatment resulted in a higher proportion of SRI responses compared with placebo.[106] Anifrolumab caused increased and more sustained target suppression of the IFN-α gene signature in Japanese patients with SLE compared with sifalimumab.[107]

### Anti-IL-6 Therapy

Tocilizumab a humanized monoclonal antibody against the α-chain of the IL-6 receptor, was tested in 16 patients with moderately active SLE.[108] Reduction in disease activity, acute phase reactants, and anti-dsDNA levels occurred. A phase II study failed to demonstrate the efficacy of sirukumab (anti-IL-6 mAb) versus placebo in patients with active PLN despite immunosuppression.[109] Conversely, administration of PF-04236921, a fully human anti-IL-6 mAb, in active SLE resulted in a higher proportion of SRI responders and reduced frequency of severe flares compared with placebo.[110] Phase III trials will determine the role of IL-6 blockade in the treatment of SLE.

## Other Therapies

### Intravenous Immunoglobulin

Intravenous immunoglobulin (IVIG) exerts immunosuppressive effects by interaction with anti-idiotypic antibodies, interference with complement and cytokines, cytolysis of target cells, induction of apoptosis through Fc receptors, and modulation of co-stimulatory molecules.[111] IVIG (400 mg/kg for 5 consecutive days, monthly for 18 months) was as effective as pulse IV CYC (1 g/m$^2$ every 2 months for 6 months, then every 3 months for 1 year) as maintenance therapy of PLN.[112] A meta-analysis of 13 studies concluded that treatment with IVIG resulted in significant reduction in the SLE disease activity scores and improvements in serum complement levels.[113] Improvements in cytopenias, especially immune thrombocytopenia and hemolytic anemia, proteinuria, arthritis, fever, arthralgia, mood changes, and psychosis have been reported.[114] Common adverse events include fever, myalgia, headache, and arthralgia; less common are aseptic meningitis, nephropathy in patients who receive sucrose-containing preparations, and thromboembolic complications in older patients with atherosclerotic risk factors. The drug is contraindicated in patients with severe IgA deficiency.

### Synthetic Tolerogens

Tolerogenic peptides aim to restore immune tolerance in lupus. Abetimus sodium (LJP-394) reduces anti-dsDNA antibodies by binding and clearance of soluble anti-dsDNA antibodies and B cell receptor cross-linking on dsDNA-specific B cells.[115] A phase III placebo-controlled trial in LN patients failed to meet its primary endpoint (prolongation of time to renal flare).[116] The spliceosomal peptide P140 (lupuzor) has, however, demonstrated benefit in SLE.[117] In a phase IIb study, patients with SLEDAI greater than or equal to 6 were randomly assigned to receive lupuzor or placebo in addition to standard of care.[118] At 24 weeks, SRI response rates were significantly higher with lupuzor than placebo (53% vs. 36%), attributed to improvements in arthritis, rash, alopecia, mucosal ulcers, and serology.

## MANAGEMENT OF SPECIFIC SYSTEMIC LUPUS ERYTHEMATOSUS MANIFESTATIONS AND TREATMENT ALGORITHMS

**KEY POINTS**

- **Sun exposure prophylaxis, topical glucocorticoids or calcineurin inhibitors, and systemic anti-malarials are recommended for skin manifestations.**
- **In moderately severe PLN, MMF or low-dose intravenous CYC is recommended; high-dose intravenous CYC is preferred in cases of severe PLN.**
- **Maintenance therapy in LN involves AZA or MMF.**
- **Glucocorticoids and/or immunosuppressives are recommended for neuropsychiatric events thought to reflect an immune/inflammatory process.**
- **Anti-platelet/anti-coagulation therapy is recommended in APS.**

European League against Rheumatism (EULAR) and ACR have developed recommendations covering the most important aspects in the diagnosis, management, and monitoring of LN[119,120] and other SLE manifestations.[121-123] In the following text we discuss the management of mucocutaneous, joint, renal, hematologic, and neuropsychiatric manifestations in patients with SLE.

## Mucocutaneous and Joint Disease

Mild malar rash and other photosensitive rashes usually respond to prophylaxis from sun exposure, but the use of protective clothing and sunscreens with high sun protection factor cannot be overemphasized. Topical GCs reduce redness and scaling. In patients with discoid lupus erythematosus (DLE), high-potency topical fluocinonide, 0.05%, was more effective than low-potency hydrocortisone, 1% (response rates 27% vs. 10%, respectively).[124] Topical calcineurin inhibitors (tacrolimus, pimecrolimus) are a useful alternative, especially for the face, because they cause less atrophic and rosacea-like effects than topical steroids.[125]

In skin disease, systemic anti-malarials, if not already prescribed, can be used alone or in combination with oral GCs (as much as 20 mg/day). HCQ was equally effective and had more favorable safety profile than the oral retinoid acitretin in DLE patients.[126] The combination of quinacrine and HCQ has also been used.[127] MTX has shown efficacy in refractory subacute cutaneous lupus erythematosus (CLE) and DLE.[128] Alternative choices are retinoids, dapsone, MMF, and IV CYC.[42,129,130] Thalidomide and IVIG are reserved for severe recalcitrant CLE cases because of potential serious neurotoxicity and high cost, respectively (Figure 81-1).[131,132]

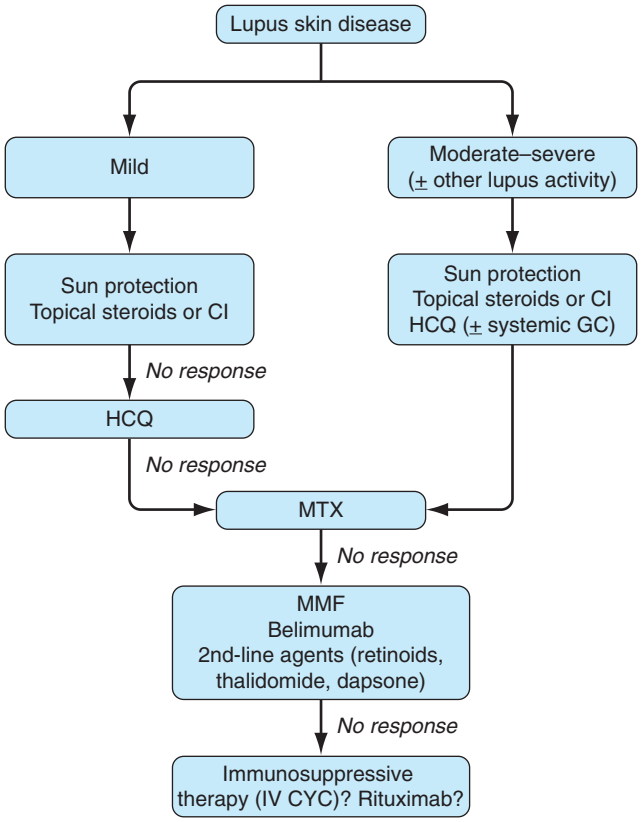

**Figure 81-1** Suggested algorithm for the management of cutaneous manifestations in systemic lupus erythematosus. See text for details. CI, Calcineurin inhibitors; GC, glucocorticoids; HCQ, hydroxychloroquine; IV CYC, pulse intravenous cyclophosphamide; MMF, mycophenolate mofetil; MTX, methotrexate. *(Modified from Kuhn A, Ruland V, Bonsmann G: Cutaneous lupus erythematosus: update of therapeutic options: part II. J Am Acad Dermatol 65:e195–e213, 2010; and Kuhn A, Ruland V, Bonsmann G: Cutaneous lupus erythematosus: update of therapeutic options: part I. J Am Acad Dermatol 65:e179–e193, 2010.)*

In mild lupus arthritis, initial therapy is anti-malarials. In persistent or aggressive disease, utilization of DMARDs is advocated, particularly MTX,[29] whereas leflunomide is used less often. Patients with inadequate response to DMARDs may benefit from belimumab treatment. RTX can be used in severe lupus arthritis or in overlap SLE-RA cases that are refractory to DMARDs.

## Lupus Nephritis

### Induction Therapy

Current therapeutic strategies in LN include an initial induction phase, aimed at substantially improving disease activity (or even attaining remission), followed by a maintenance phase, in which the goal is to maximize the therapeutic effect and consolidate the response. Risk stratification, according to renal pathology and patient demographic, clinical, and laboratory characteristics, enables the identification of patients at risk for renal dysfunction, ESRD, or both, who may benefit from aggressive cytotoxic therapy (Table 81-5).[133,134] Figure 81-2 and Table 81-6 summarize the treatment recommendations for LN.[119]

### Treatment of Renal Flares

Approximately 30% to 50% of patients with moderate to severe PLN will relapse after achieving partial or complete remission.[135,136] Nephritic flares are characterized by active urine sediment and reproducible increases of serum creatinine (Cr) (≥30% increase) and may adversely affect renal prognosis[137]; proteinuric flares without significant changes in renal function have a more benign prognosis. Risk factors for progression to ESRD after a nephritic flare are patients with marked loss of renal function (Cr >2 mg/dL) at the time of response, partial response to therapy, and high chronicity and activity indices at renal biopsy. Mild to moderate flares (stable Cr, subnephrotic proteinuria) may be treated with GC in combination with AZA or MMF. Calcineurin inhibitors (alone or added to existing immunosuppressive therapy) have also demonstrated efficacy. For severe nephritic flares, (re-)institution of cytotoxic therapy with monthly pulses of IV CYC and IV MP is the authors' preferred approach, with MMF considered as an alternative agent. RTX has also been successfully used.[88]

## Central Nervous System Disease

Neuropsychiatric SLE (NPSLE) represents a clinical challenge because of the often-ambiguous attribution of neuropsychiatric syndromes to SLE per se and the paucity of controlled trials (Figure 81-3).[122] Immunosuppressive therapy (GCs alone or in combination with AZA for mild to moderate cases, or IV CYC for severe ones) is advocated for neuropsychiatric events thought to reflect an immune/inflammatory process (particularly acute confusional state, aseptic meningitis, myelitis, optic neuritis, refractory seizure disorder, peripheral neuropathies, or psychosis) or when they occur in the context of active generalized lupus, following exclusion of non–SLE-related causes.[43,138] Antiplatelet or anti-coagulation therapy is recommended for events related to anti-phospholipid antibodies (APAs),

**TABLE 81-5** Definitions of Lupus Nephritis Severity

| | |
|---|---|
| **Proliferative Nephritis** | |
| Mild | 1. Class III nephritis without severe histologic features (crescents, fibrinoid necrosis)*; low chronicity index (≤3); normal renal function; non-nephrotic range proteinuria |
| Moderately severe | 1. Mild disease as defined above with partial or no response after the initial induction therapy, or delayed remission (>12 mo), *or*<br>2. Focal proliferative nephritis with adverse histologic features or reproducible Cr increase ≥30%, *or*<br>3. Class IV nephritis without adverse histologic features |
| Severe | 1. Moderately severe as defined above, but not remitting after 6-12 mo of therapy, *or*<br>2. Proliferative disease with impaired renal function and fibrinoid necrosis or crescents in >25% of glomeruli, *or*<br>3. Mixed membranous and proliferative nephritis, *or*<br>4. Proliferative nephritis with high chronicity alone (chronicity index >4) or in combination with high activity (chronicity index >3 and activity index >10), *or*<br>5. Rapidly progressive glomerulonephritis (doubling of Cr within 2-3 mo) |
| **Membranous Nephropathy** | |
| Mild | 1. Non-nephrotic range proteinuria with normal renal function |
| Moderate | 2. Nephrotic range proteinuria with normal renal function at presentation |
| Severe | 3. Nephrotic range proteinuria with impaired renal function at presentation (≥30% increase in Cr) |

*Concomitant therapy with corticosteroids or immunosuppressive drugs, or both, may modify urinary sediment and histologic findings and should be taken into consideration.
Cr, Serum creatinine.

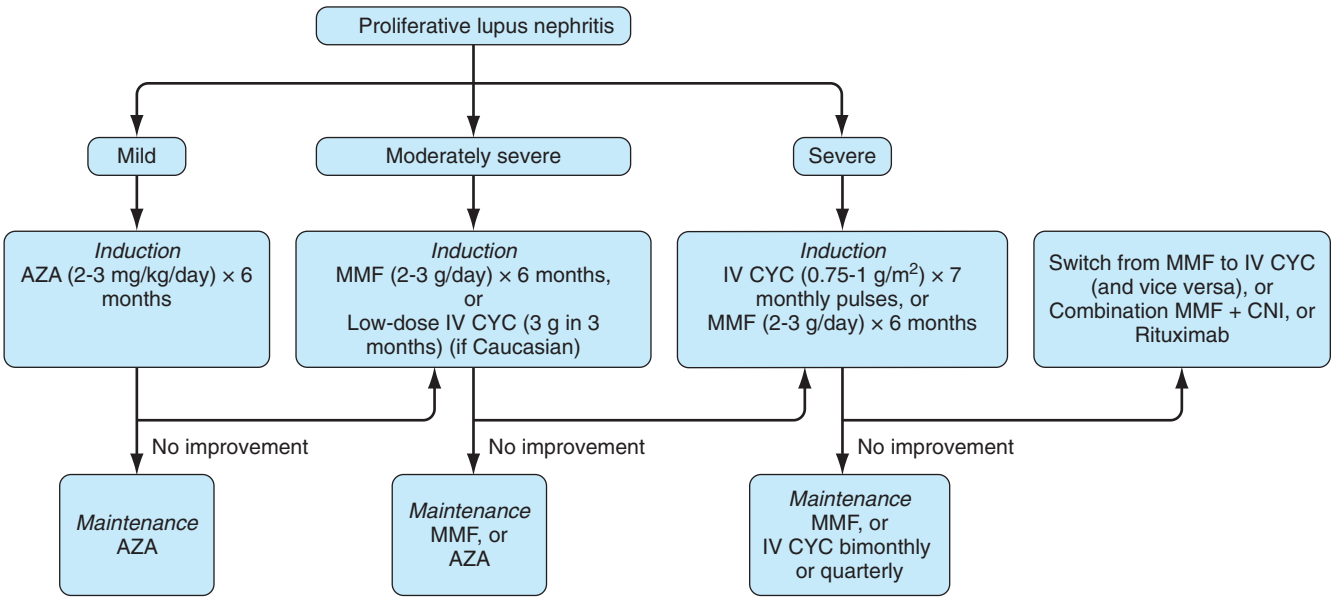

**Figure 81-2** Recommended treatment of proliferative lupus nephritis. Improvement (reduction in proteinuria, stabilization or increase in glomerular filtration rate) is assessed within the first 3 to 4 months after treatment initiation. All induction regimens include pulse intravenous methylprednisolone (IV MP) (1 g/pulse × 3), followed by oral prednisone (0.5-0.6 mg/kg for the first 4 weeks of induction, then tapered). See also Table 81-6. AZA, Azathioprine; CNI, calcineurin inhibitors; IV CYC, intravenous cyclophosphamide; MMF, mycophenolate mofetil.

especially for thrombotic cerebrovascular disease.[139,140] In severe NPSLE refractory to cytotoxic therapy, RTX can be efficacious.[141] Memantine (an N-methyl-D-aspartate [NMDA] receptor antagonist) failed to improve cognitive performance in patients with SLE.[142] Immunosuppressive therapy is usually not warranted for cognitive dysfunction in SLE, which typically follows a benign course.

## Hematologic Disease

Peripheral cytopenias are common but usually mild in SLE. A thorough clinical and laboratory evaluation is necessary to exclude offending drugs or other secondary causes. Mild cytopenias require no specific therapy other than regular monitoring. In more severe cases (platelet count < $50 \times 10^3$/mm$^3$ or active bleeding, neutrophil count <1000/mm$^3$), GCs are the mainstay of treatment. Steroid-sparing agents (AZA and CsA) can be added during steroid tapering. Resistant life-threatening cytopenias may require potent immunosuppressive or biologic therapy. The investigation and management of cytopenias in patients with SLE is outlined in Table 81-7.

## Presence of APAs/APS

APAs (anti-cardiolipin [aCL], anti–$\beta_2$-glycoprotein I [anti-$\beta_2$GPI], and lupus anti-coagulant [LAC]) are encountered in 30% to 40% of SLE and confer increased risk for

**TABLE 81-6** Treatment of Lupus Nephritis

| |
|---|
| **Class I-II LN** |
| Renin-angiotensin-aldosterone system blockade is recommended. |
| GCs (prednisone, 0.5-1 mg/kg/day for 4 to 6 weeks, then tapered): in cases of proteinuria >1 g/day, active urine sediment, histologic features of podocytopathy, or extrarenal disease activity. Three consecutive daily pulses of IV MP may expedite remission and allow for the use of lower GC doses (0.5 mg/kg/day). |
| Consider immunosuppressive therapy (AZA, 1-2 mg/kg/day) to decrease cumulative steroid dose. |
| **Class III-IV (± V) LN** |
| **Initial (Induction) Treatment**<br>Pulses IV MP (750-1000 mg × 3 days), followed by oral prednisone, 0.5 mg/kg/day; higher starting dose may be used if there is significant extrarenal lupus activity |
| Immunosuppressive treatment<br>AZA (2-2.5 mg/kg/day): consider only in white patients with mild disease<br>Low-dose IV CYC (500 mg × 6 every two weeks doses): in white patients with moderately severe disease<br>MMF (3 g/day; or equivalent dose of eMPA): in moderately severe disease; second-line in severe disease; preferable in black or Hispanic patients<br>High-dose IV CYC (0.75-1 g/m$^2$ × 7 monthly pulses): in severe disease |
| **Subsequent (Maintenance) Treatment**<br>Patients who improve (reduction in proteinuria with stabilization or increase in GFR) on induction treatment may continue with maintenance treatment |
| Gradual tapering of GCs: 7.5 to 15 mg of prednisone equivalent on alternate days |
| Immunosuppressive treatment<br>AZA (2 mg/kg/day): preferred if induction with IV CYC or pregnancy contemplation<br>MMF (2 g/day): preferred if induction with MMF or in severe LN<br>IV CYC (quarterly pulses for 1 year after response): in severe LN |
| Duration of maintenance treatment: 3 years; early (before 18-24 months after renal response) tapering or withdrawal of immunosuppressive treatment is associated with increased risk for flares |
| **Class V LN** |
| Renin-angiotensin-aldosterone system blockade is recommended. |
| Consider immunosuppressive therapy in cases of proteinuria >1 g/day (particularly if nephrotic-range proteinuria), reduced GFR. |
| **Initial (Induction) Treatment**<br>Oral prednisone, 0.5 mg/kg/day; consider initial pulses IV MP (750-1000 mg ×3 days) in severe cases |
| Immunosuppressive treatment<br>AZA (2-2.5 mg/kg/day): consider in mild disease<br>CNIs (cyclosporine A, tacrolimus): in mild or moderately severe disease |
| MMF (3 g/day; or equivalent dose of eMPA): in moderately severe disease or severe disease |
| High-dose IV CYC (0.75-1 g/m$^2$ × 7 monthly pulses): in moderately severe or severe disease |
| **Subsequent (Maintenance) Treatment**<br>Patients who improve (reduction in proteinuria with stabilization or increase in GFR) on induction treatment may continue with maintenance treatment |
| Gradual tapering of GCs: 7.5-15 mg of prednisone equivalent on alternate days |
| Immunosuppressive treatment<br>AZA (2 mg/kg/day): preferred if induction with IV CYC or pregnancy contemplation<br>CNIs (cyclosporine A, tacrolimus): in mild or moderately severe disease; careful consideration of risks for hypertension, nephrotoxicity or metabolic adverse effects<br>MMF (2 g/day): preferred if induction with MMF; in moderately severe or severe disease |
| **Therapeutic Goals and Refractory Disease** |
| Early response to therapy at 6 months (defined as normalization of Cr level and reduction in proteinuria by at least 50% or to less than 1 g/day) is a predictor of good long-term renal outcome.[196,197] |
| Failure to achieve improvement in renal function and proteinuria after the initial 3 to 4 months, or response after 6 to 12 months of therapy should precipitate decisions about treatment switching/intensification. |
| Microscopic hematuria or non-nephrotic proteinuria may not clear for several months, and complete renal response (defined as proteinuria <0.5 g/day with normal or near-normal [±10%] GFR) may occur at an average of 1.5 to 2 years after therapy.[198] |
| Discontinuing or switching immunosuppressive therapy because of lack of achieving complete renal response before completing at least 2 years of treatment is not justified unless there is definite disease worsening (reproducible increase in Cr and/or increase in proteinuria). |

AZA, Azathioprine; Cr, serum creatinine; CYC, cyclophosphamide; eMPA, enteric-coated mycophenolate sodium; IV, intravenous; MP, methylprednisolone; MMF, mycophenolate mofetil.

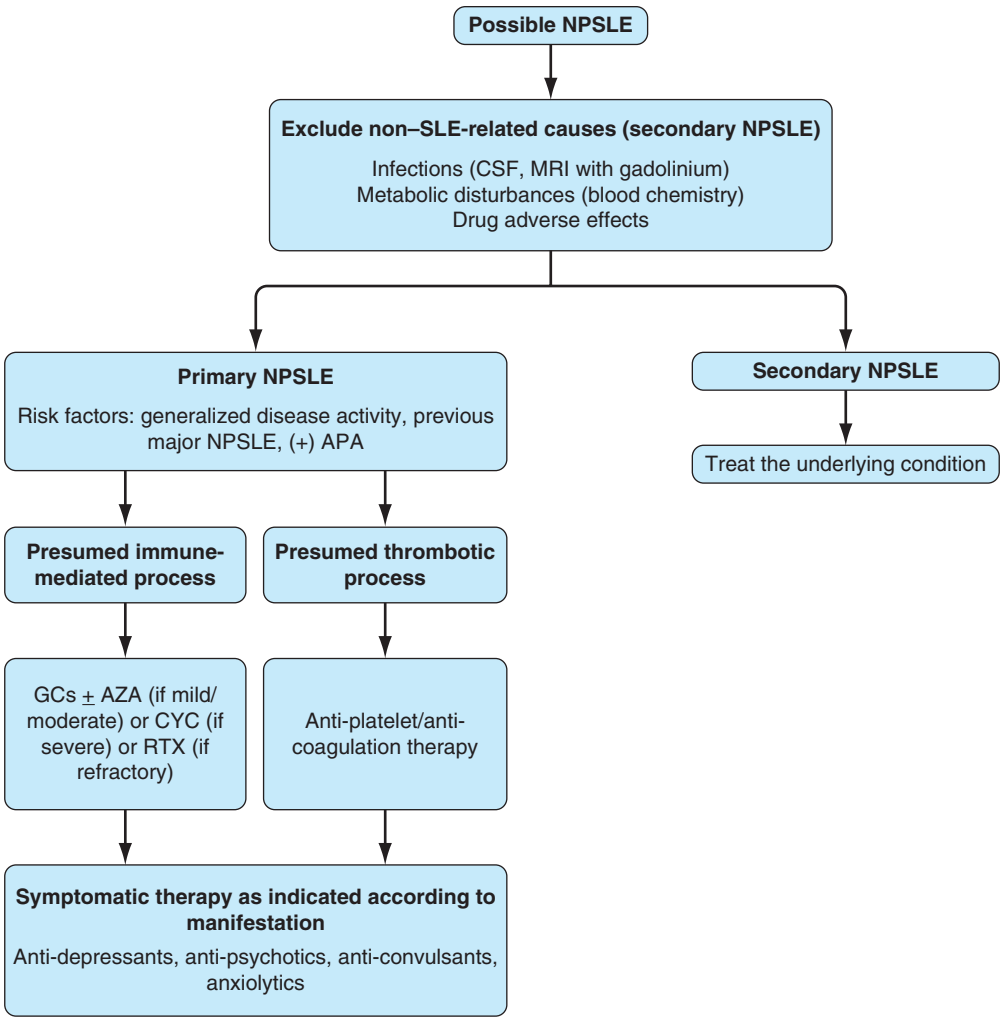

**Figure 81-3** Assessment and management of patients with systemic lupus erythematosus who are seen with neuropsychiatric manifestations. APA, Anti-phospholipid antibodies; AZA, azathioprine; CSF, cerebrospinal fluid analysis; CYC, cyclophosphamide; GC, glucocorticoids; MRI, magnetic resonance imaging of brain and/or spine that includes T1, T2, FLAIR, and diffuse-weighed imaging protocols; NPLSE, neuropsychiatric systemic lupus erythematosus; RTX, rituximab.

thrombotic events. The combination of vascular thrombosis or obstetric morbidity, or both, and persistently positive APAs measured at least 12 weeks apart, defines APS.[143] The principles of APS treatment (anti-platelet or anti-coagulation, target INR) do not differ between primary APS and SLE-APS and are described in detail in Chapter 82.

A distinct type of small-vessel vaso-occlusive nephropathy with histologic features of thrombotic microangiopathy and chronic vascular lesions, termed *APS nephropathy*, should be suspected in APA-positive patients with SLE with hypertension, proteinuria (usually subnephrotic range), hematuria, and renal impairment.[144] These patients may benefit from anti-platelet or anti-thrombotic therapy, but development of ESRD is common.[145] Aberrant activation of the mammalian target of rapamycin (mTOR) pathway has been documented in APS nephropathy and APS-related renal vascular lesions superimposed on inflammatory LN, suggesting that agents targeting this pathway may prove useful for these patients.[146]

## REFRACTORY DISEASE, PREGNANCY, AND CHILDREN

**KEY POINTS**

- **Pregnancy outcome in women with SLE is optimal when the disease is quiescent for at least 6 months before conception.**
- **Continuation of HCQ during pregnancy is associated with improved maternal and fetal outcomes.**
- **The risks of treatment during pregnancy must be weighed against the risks of an untreated SLE flare.**

### Treatment of Refractory Systemic Lupus Erythematosus

IV CYC in combination with IV MP has long been considered the treatment of choice for most patients with severe, life-threatening lupus. MMF may rescue a few refractory patients with SLE, including subacute CLE[130] and LN cases

**TABLE 81-7** Management of Hematologic Manifestations in SLE[84,199-201]

| |
|---|
| Exclude offending drugs or other secondary causes |
| History of drug exposure, infections, traveling to endemic regions |
| Clinical examination: signs of infection, splenomegaly, lymphadenopathy, skin hemorrhagic lesions |
| Peripheral blood smear examination (morphology of cells; rule-outs: hematologic malignancy, myelodysplastic syndrome, microangiopathic hemolytic anemia [MAHA] / thrombotic thrombopenic purpura [TTP] |
| Workup for anemia (ferritin, TIBC, folic acid, vitamin $B_{12}$, reticulocyte index) and hemolysis (reticulocyte index, LDH, bilirubin, Coombs IgG, haptoglobulin) |
| Workup for infections (as indicated by history and clinical examination) |
| High-yield indications for bone marrow examination: age >60 years, serum iron >90 µg/dL, mean corpuscular volume (MCV) >90 fL, serum monoclonal band, pancytopenia, history of exposure to myelotoxic drugs, absolute neutrophil count (ANC) <500/µL (on repeated tests), peripheral blood smear findings suggestive of bone marrow disorder |
| Immunosuppressive treatment |
| Mild cytopenias require no specific therapy other than regular monitoring |
| Consider immunosuppressive treatment if: autoimmune hemolytic anemia (AIHA) with hemoglobin <10 g/dL, leukopenia with white blood cell count <2500/µL or ANC <1000/µL, thrombocytopenia with platelet count <50-70 ×1000/µL |
| First-line treatment: (1) GCs (as much as 1 mg/kg/day prednisone equivalent); consider pulses IV MP (500-1000 mg × 3 days) to allow for lower oral GC (0.5 mg/kg/day); (2) AZA (2 mg/kg/day) or CsA as steroid-sparing agent (careful monitoring of white blood cell count) |
| Second-line treatment (refractory/relapsing disease): (1) IV CYC (AIHA, thrombocytopenia), (2) rituximab (AIHA, thrombocytopenia, leucopenia), (3) IVIG (short-term recovery of platelets), (4) CsA (neutropenia, thrombocytopenia) |
| Third-line treatment: danazol, MMF, plasma exchange (severe MAHA/TTP-like) |
| Additional or supportive treatment |
| Red blood cells transfusion: defer until hemoglobin <7 g/dL |
| Recombinant erythropoietin: if co-existing chronic kidney disease (stage 4-6) or anemia of chronic disease |
| Prophylaxis or treatment with broad-spectrum antibiotics (as recommended) |
| Recombinant G-CSF: only if ANC <500/µL and sepsis; use at lowest possible doses and until ANC >1000/µL |
| TPO-receptor agonists (romiplostin, eltrombopag): safe and efficacious in immune thrombocytopenia; require repeated administration; can be used when splenectomy is not favored or is contraindicated |
| Splenectomy: in selected patients with severe refractory AIHA or thrombocytopenia, when there is no lupus activity in other major organs; prophylactic measures for avoidance of infectious complications; post-splenectomy immunosuppressive treatment is usually required |

AZA, Azathioprine; Cr, serum creatinine; CsA, cyclosporin A; CYC, cyclophosphamide; GC, glucocorticoids; Ig, immunoglobulin; IV, intravenous; LDH, lactate dehydrogenase; MMF, mycophenolate mofetil; TIBC, total iron-binding capacity.

with inadequate response to CYC.[147] Calcineurin inhibitors have also shown efficacy in resistant-to-standard immunosuppressive therapy lupus,[148] particularly LN, where benefits of combination therapy with MMF have been illustrated.[79,80] Belimumab is an option for patients with active mucocutaneous and musculoskeletal manifestations that do not respond to standard of care treatment and/or who relapse upon tapering of GC.[93] Mounting evidence supports the beneficial effects of RTX (alone or in combination with IV CYC) in refractory SLE.[88,149] Higher response rates have been reported for skin, blood, CNS, and renal manifestations. For selected patients with CNS involvement, autoimmune thrombocytopenia, or APS, IVIG may be considered as an adjunct therapy. Synchronized therapy with plasmapheresis and pulse IV CYC has been used in severe PLN cases.[150] High-dose chemotherapy with autologous hematopoietic stem cell transplantation (HSCT) remains an experimental procedure to be considered in critically ill patients with SLE.[151]

**TABLE 81-8** Approach to the Management of Pregnancy in Systemic Lupus Erythematosus

| |
|---|
| Planning of pregnancy |
| Ensure that lupus is inactive for at least 6 months |
| Reassure patient: small risk for major flare |
| Discourage pregnancy if Cr >2 mg/dL |
| Drugs allowed during pregnancy: GCs, HCQ, AZA, CsA |
| Determine APAs and other antibodies that may be of relevance (anti-SSA, anti-SSB) |
| Obtain baseline serology and chemistry tests (Cr, Alb, uric acid, anti-dsDNA, C3/C4) |
| Be aware of the small risk for CHB, especially in women with both anti-SSA and anti-SSB antibodies or with a prior episode of CHB. In such cases, may monitor for CHB between 18 and 24 weeks of gestation |
| Monitor closely blood pressure and proteinuria. Should this develop, differentiate between active nephritis and pre-eclampsia |
| Presence of generalized lupus activity, active urine sediment, and low serum complement are in favor of lupus nephritis |
| For patients with APS, consider combined heparin and aspirin to reduce risk for pregnancy loss and thrombosis. Patients with APA may be treated with aspirin, although there are no adequate data to support its use |

Alb, Serum albumin; APA, anti-phospholipid antibodies; APS, anti-phospholipid antibodies/anti-phospholipid syndrome; AZA, azathioprine; CHB, congenital heart block; Cr, serum creatinine; CsA, cyclosporin A; dsDNA, double-stranded DNA; GCs, glucocorticoids; HCQ, hydroxychloroquine.

## Treatment of Lupus in Pregnancy

Pregnancy may increase disease activity and precipitate the appearance of flares (13% to 74%), which are usually mild. Pregnancies in patients with lupus, especially in patients with a history of LN or positive APA, are considered high risk for maternal and fetal complications, including pre-eclampsia, pregnancy loss, and pre-term birth.[152] The management of a pregnant woman with an SLE flare is challenging and should be dealt with on a multidisciplinary basis (Table 81-8).

Neonatal lupus occurs in some babies born to mothers with anti-SSA/Ro or anti-SSB/La antibodies. The most serious complication is neonatal complete heart block (CHB), which occurs in as many as 2% of such pregnancies and carries a 20% to 30% mortality risk. The risk of recurrence in a mother who has already borne a child with CHB ranges from 14% to 19%.[153] Therefore all women with SLE

should be screened for anti-Ro/La antibodies. The most vulnerable period for the development of conduction disturbances is between weeks 18 and 26 of gestation, during which anti-Ro/La–positive patients should be evaluated with weekly fetal Doppler echocardiography for the prompt identification of conduction anomalies, mainly PR interval prolongation. If CHB develops, no modality has been shown to reverse it. In contrast, in pregnant women with anti-Ro antibodies, first-degree block may be reversed by fluorinated GCs such as dexamethasone (4 mg/day) initiated at the time of diagnosis and continued throughout pregnancy.[154] HCQ has been associated with reduced risk for recurrences of cardiac neonatal lupus,[155] contrary to IVIG which has demonstrated no beneficial effect.[156,157]

Regarding breastfeeding, the American Academy of Pediatrics (AAP) states that nursing is permissible for women receiving GC, but the interval between dose and nursing should be at least 4 hours if the prednisone dosage is greater than 20 mg/day. Anti-malarials may be continued during lactation, whereas AZA is not recommended because of possible risk for immunosuppression, carcinogenicity, and growth restriction of the child. MTX, MMF, CsA, leflunomide, and CYC are also contraindicated.

## COMORBIDITIES

**KEY POINTS**

- **In a patient with SLE with possible infection, the clinical syndrome, history of epidemiologic exposures, and degree of immunosuppression should be considered.**
- **Immunizations are safe and effective in stable, inactive patients with SLE. Live vaccines are contraindicated in patients taking immunosuppressive drugs or high-dose glucocorticoids.**
- **Hemodialysis may be preferred versus peritoneal dialysis in end-stage renal disease. Patients should be evaluated for renal transplantation.**
- **Strict adherence to general population guidelines for primary prevention of cardiovascular disease is recommended.**
- **Cervical dysplasia is increased in women with lupus. Human papillomvirus vaccination should be considered, similarly to the general population.**

### Infections and Immunizations

#### Risk Factors and General Management

Infections account for 20% to 55% of all deaths in patients with SLE. A broad spectrum of infections has been reported, including bacterial, mycobacterial, viral, fungal, and parasitic infections. The respiratory system, urinary tract, and the CNS are the most commonly involved sites.[158] Risk factors include increased clinical or serologic lupus activity, or both, at baseline; major organ involvement (especially renal and lung involvement); lymphopenia; persistent neutropenia (<1000/mm$^3$); hypoalbuminemia (especially for severe CNS infections); high dose of GC (each increase of 10 mg/day prednisone is associated with an 11-fold increased risk for serious infection); and prior (within the last 6 months) use of immunosuppressive drugs (especially AZA and CYC).[159]

The evaluation of a patient with lupus who receives immunosuppressive therapy and is seen with symptoms or signs suggestive of infection is complicated by the fact that infections can mimic a lupus flare (Figure 81-4). Findings that favor the diagnosis of infection include the presence of shaking chills, leukocytosis and/or neutrophilia (especially in the absence of steroid therapy), increased numbers of band forms or metamyelocytes on peripheral blood smear, and concomitant immunosuppressive therapy.[160,161] SLE fever is favored by the presence of leukopenia (not explained by cytotoxic therapy), normal or only slightly increased C-reactive protein, low C3/C4, and elevated anti-DNA antibodies. If fever fails to resolve in a patient receiving prednisone, 20 to 40 mg daily, it is likely that that fever is to the result of infection. Elevated serum procalcitonin levels have been reported to be predictive of bacterial or mycotic infections, although their diagnostic utility in patients with systemic autoimmune diseases has been questioned.[162] Pending microbiology results, anti-microbial therapy (including broad-spectrum antibiotics in suspected nosocomial infection) is recommended to reduce adverse outcomes.

#### Immunizations

Although vaccination may hypothetically induce polyclonal cell activation in lupus precipitating a flare, it is felt to be safe.[163] Vaccines, however, should not be given to patients with active disease. Inactivated live vaccines (measles, mumps, rubella, polio, varicella-zoster virus (VZV), and vaccinia [smallpox]) are contraindicated in patients taking immunosuppressive drugs or prednisone at a dose greater than 20 mg/day. Influenza vaccine is safe and effective, although seroprotection and seroconversion rates are lower than those in healthy controls; booster vaccination does not increase antibody titers in annually vaccinated patients. Pneumococcal vaccine is also safe, but the resultant antibody titers may be decreased in patients with SLE; use of GC may contribute to blunted antibody responses.[164] Protective immune response can be achieved safely in patients with SLE with both tetanus toxoid and *Haemophilus influenzae* type B in addition to pneumococcus.

According to the Advisory Committee on Immunization Practices (ACIP) guidelines and EULAR guidelines,[165] individuals older than 60 years should be vaccinated with a single dose of VZV vaccine. This is a live-attenuated vaccine and should be administered at least 14 days before starting immunosuppressive therapy, or it should be deferred for at least 1 month after discontinuation of high-dose GC or intensive immunosuppressive therapy. Hepatitis B immunization with recombinant vaccine seems to be efficacious and safe in inactive patients with SLE treated with low-dose GC and not receiving immunosuppressive drugs.[166]

### Chronic Kidney Disease and End-Stage Renal Disease

#### Risk Factors and Dialysis

Approximately 10% to 20% of patients with SLE will develop ESRD. Clinical predictors are abnormal Cr values at presentation, delay in treatment initiation, failure

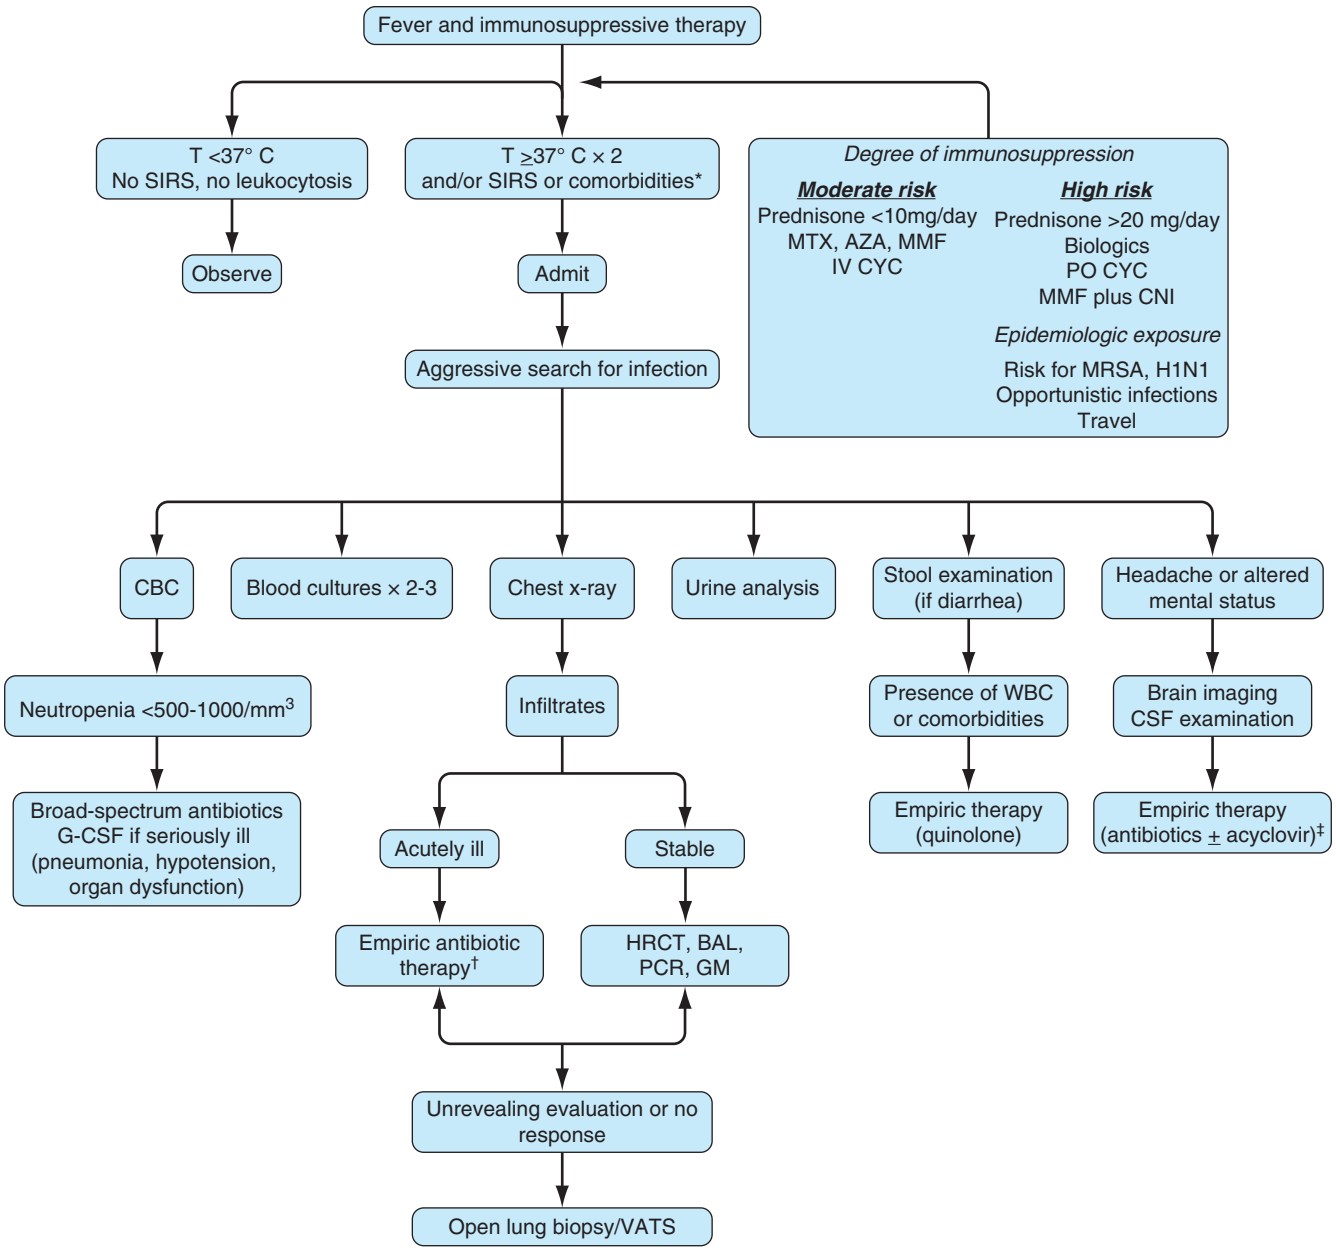

**Figure 81-4** Initial assessment and management of patients with systemic lupus erythematosus who receive immunosuppressive therapy and are seen with fever or other symptoms and signs suggestive of infection. *Systemic inflammatory response syndrome (SIRS): T ≥38° C or <36° C, tachycardia (heart rate >90/min), tachypnea (respiratory rate >20/min), white blood cells (WBC) >12,000/mm$^3$; comorbidities: age older than 65 years, diabetes, chronic cardiopulmonary disease. †Consider empiric therapy for *Pneumocystis* pneumonia in severe hypoxemia or diffuse pulmonary infiltrates. ‡Consider tuberculosis and other opportunistic central nervous system (CNS) infections. AZA, Azathioprine; BAL, bronchoalveolar lavage; CBC, complete blood count; CSF, cerebrospinal fluid; G-CSF, granulocyte colony-stimulating factor; GM, galactomannan; H1N1, influenza H1N1; HRCT, high-resolution chest tomography; IV CYC, intravenous cyclophosphamide; MMF, mycophenolate mofetil; MRSA, methicillin-resistant *Staphylococcus aureus*; MTX, methotrexate; PCR, polymerase chain reaction; T, temperature; VATS, video-assisted thoracoscopy. *(Modified from Papadimitraki ED, Bertsias K, Chamilos MD, Boumpas DT: Systemic lupus erythematosus: cytotoxic drugs. In Tsokos G, Buyon JP, Koike T, Lahita RG, editors:* Systemic lupus erythematosus*, ed 5, St. Louis, 2010, Elsevier, pp 1083–1108.)*

to achieve remission, and systolic hypertension.[133,167,168] Patients with rapid deterioration of renal function are more likely to have a reversible physiologic (dehydration, infection, acute tubular necrosis) or pathologic (crescentic glomerulonephritis) component accounting for their renal insufficiency. In these patients, immunosuppressive therapy (pulse of IV MP and IV CYC 0.4 to 0.5 g/m$^2$, administered 8 to 10 hours before dialysis) may continue during dialysis.

The 5-year survival rate of patients with SLE on dialysis approximates 80% to 90%, comparable with that in non-SLE dialysis patients.[169] Hemodialysis may be the first choice of renal replacement therapy, especially for patients who are still on immunosuppressive therapy, due to increased rates of infectious complications (most commonly peritonitis) in patients on chronic ambulatory peritoneal dialysis (CAPD). Irrespective of the dialysis mode, most patients experience a decline in lupus activity. Discontinuation of

cytotoxic therapy may be considered in patients with steadily rising Cr to greater than or equal to 5 mg/dL with inactive urine sediment, renal biopsy showing exclusively scarring and atrophy, or contracted renal size. Judicious use of GCs and immunosuppressive drugs is essential to minimize the risk for septic complications. Cardiovascular morbidity and mortality are also increased in patients with ESRD, underscoring the need for tight control of atherosclerotic risk factors.[170]

### Renal Transplantation

Renal transplantation is a viable alternative for lupus patients with ESRD. Graft and patient survival rates are generally comparable with those in other patient groups.[171] Results are superior with living compared to cadaveric donor transplantation. Pre-emptive transplantation should be considered because it is associated with superior graft and patient outcomes. Nevertheless, a period of at least 3 months on dialysis may allow some patients to recover adequate renal function for significant time periods.

There are no prospective studies comparing various immunosuppressive regimens after renal transplantation in SLE. Calcineurin inhibitors are generally included in the induction phase (6 to 12 months) to prevent acute transplant rejection.[172] Due to potential nephrotoxicity and adverse metabolic effects, their use should be minimized during the maintenance phase and other immunosuppressive agents (MMF, AZA) should preferentially be employed. Recurrence of LN (usually mild mesangial proliferative disease) in the renal allograft is rare (3%) and not a major cause of graft loss. Risk factors for recurrence include black race, female gender, age younger than 33 years, and living-donor transplantation.[173,174] APS has been associated with post-transplant renal thrombosis and poor graft outcome and warrants anti-coagulation therapy.[175]

## Cardiovascular Morbidity

Traditional risk factors fail to fully account for the increased risk for atherosclerotic CVD in patients with SLE.[176] Biomarkers such as pro-inflammatory high-density lipoprotein (HDL) or high-sensitivity C-reactive protein are elevated in lupus patients and correlate with carotid intima media thickness (CIMT), a surrogate marker for subclinical atherosclerosis.[177,178]

Tight control of CVD risk factors is recommended for patients with SLE. The importance of smoking cessation cannot be overemphasized. Hypertension should be controlled below 130/80 mm Hg; for most cases, ACE inhibitors or angiotensin receptor blockers (ARBs), or both, are the initial treatments of choice. For dyslipidemia, two recent RCTs in adult and pediatric SLE failed to show benefits of atorvastatin in CIMT and coronary artery calcium.[179,180] The relatively small sample size and duration may have partly contributed to the negative results. Accordingly, lipid-lowering therapy in lupus should follow the guidelines for the general population.[181] Aggressive control of dyslipidemia (target LDL-C <100 mg/dL and triglycerides <150 mg/dL) is recommended for patients with multiple risk factors, especially those with at least moderate lupus or on chronic GC therapy.

## Osteoporosis

Ongoing disease activity, premature menopause caused by use of immunosuppressive drugs, relative vitamin D deficiency (associated with sun avoidance), and the use of systematic GCs all contribute to reduced bone mineral density (BMD) in SLE.[182] Quality indicators suggest that (1) all patients with SLE receiving prednisone greater than or equal to 7.5 mg/day for 3 or more months should undergo BMD testing unless already on anti-resorptive or anabolic therapy and receive osteoporosis prophylaxis with calcium and vitamin D supplements, and (2) patients receiving prednisone greater than or equal to 7.5 mg/day for 1 or more months and having a central T score of −2.5 or less or a history of fragility fracture should be treated with an anti-resorptive or anabolic agent unless contraindications exist.[183] This prednisone dosage is higher than the guideline proposed by the ACR for prevention of steroid-induced osteoporosis (5 mg/day) in the general population. The authors recommend osteoporosis prophylaxis with daily prednisone doses of greater than or equal to 5 mg for postmenopausal women and greater than or equal to 7.5 mg for pre-menopausal women.

## Malignancy in Lupus

Patients with SLE have a marginally increased risk for overall cancer development (standardized incidence ratio [SIR], 1.14).[184] Certain types of malignancies occur more commonly in patients with SLE, in particular non-Hodgkin's lymphoma (NHL), cervical and lung cancer, and some rare types (e.g., hepatobiliary tract, anal canal, and vagina/vulva cancer).[185] Both immunosuppressive therapy and the disease *per se* have been implicated for this increased risk.

NHL is associated with SLE (SIR, 3.6-4.3).[184,186] The most common subtype is diffuse large B cell lymphoma. Hodgkin's lymphoma (HL) is also more frequent (SIR, 3.2).[187, 188] A high index of suspicion is necessary for early detection of lymphoma, followed by aggressive investigation and a low threshold for lymph node biopsy.

Cervical dysplasia is increased in women with SLE (pooled OR, 8.7[189]) as a result of impaired clearance of human papillomavirus (HPV) resulting from exposure to immunosuppressive agents. Screening cervical cytology with HPV testing is recommended for all female patients with SLE; for women with detectable HPV DNA, subsequent screening with cervical cytology should be performed every 6 months. For the remaining patients, annual rescreening is sufficient. EULAR recommends HPV vaccination for women with SLE until the age of 25 years, similar to the general population.[165] Increased risk for lung cancer may be smaller than previously believed, yet higher in smokers (SIR, 1.16-1.30).[184,190] Patients with SLE have a slightly reduced risk of certain nonhematologic cancers (breast, ovarian, endometrial, and prostate: SIRs, 0.66 to 0.77).[184]

## Emergencies in Patients with Lupus

Patients with SLE may visit the emergency department (ED) for complications related to lupus itself or its therapy, or for unrelated reasons. Critical questions confronting the clinician are (1) whether the event is related to lupus and

(2) whether in the presence of lupus the management should differ. SLE-related emergencies frequently occur when disease is active. Poor compliance, low education level, severity of the underlying disease, and higher damage scores are risk factors for hospitalization.

Patients with SLE may also develop life-threatening organ dysfunction, related to disease activity or immunosuppressive therapy, severe enough to require admission to the intensive care unit (ICU). Infections are the leading cause of admission (45% to 61%). Overall mortality is high, although it has declined during the past decade (from 47% to 24%).[191] An aggressive search for infection and empiric anti-microbial therapy are crucial. When it is not clear whether the underlying process is related to infection or active disease, empiric anti-microbial therapy together with high-dose GC (0.5 to 1 mg/kg/day) may suffice. Once infection has been ruled out, pulse steroids or CYC, or both, may be used. Agents such as IVIG, plasmapheresis, and RTX may be considered as adjuvant therapy in life-threatening disease or in cases of deterioration or inadequate response following 1 to 2 weeks of therapy.

## WOMEN'S HEALTH ISSUES

**KEY POINTS**

**Gonadotropin-releasing hormone analogues decrease rates of gonadal failure in young women with severe SLE treated with CYC.**

**Contraceptive methods, including hormone agents, are generally safe for most patients with SLE.**

Premature ovarian failure is an age- and dose-dependent adverse effect of CYC therapy, whereas male gonadal toxicity may be observed with as little as 7 g cumulative CYC dose. Strategies to preserve fertility in post-pubertal SLE women include hormonal contraceptives, gonadotropin-releasing hormone (GnRH) antagonists, and embryo and oocyte cryopreservation. Individual patient preferences should be considered. Some authors recommend a GnRH antagonist–based protocol in CYC-treated female patients to protect against premature ovarian failure. In men, administration of testosterone and sperm banking represent valid strategies for preservation of testicular function and/or fertility (see Table 81-3).[192]

Hormonal contraceptive methods are generally safe for most patients with SLE with stable, inactive disease. Two RCTs found no significant increase in flares in patients without severe disease activity at study entry, and a systematic review concluded that benefits of use outweigh potential risks for most contraceptive methods.[193] However, women with APAs should avoid combined hormonal methods because of increased risk for thrombosis. Coexisting conditions such as severe thrombocytopenia, atherosclerosis, hypertension, and venous thrombosis could also make certain contraceptives less advisable.

Women with SLE may experience lower urinary tract symptoms, often accompanied by voiding dysfunction (small bladder capacity, low urinary flow rate).[194] The approach to investigation and management of recurrent urinary tract infections is similar to that in the general population; control of disease activity may prevent bladder dysfunction. Lupus mastitis represents a rare form of lupus panniculitis that occurs in 2% of women with SLE and may clinically mimic breast carcinoma.[195] GC treatment is generally effective, but refractory forms may necessitate surgical excision.

## CONCLUSION

This past decade has witnessed major advances in defining risk factors and phenotypes, elucidating pathogenesis, and optimizing treatment. Recognition of adjuvant-like factors that promote the production of type I interferon via Toll-like receptors offers new targets for therapy in addition to those targeting B and T cells. Exploration of the genetic and environmental factors that determine susceptibility to disease may eventually lead to the identification of individuals at risk and elucidate the primary events that cause autoimmunity. In contrast to monogenic diseases, the expansion of personalized medicine in lupus awaits a more complete description of predisposition. Genome-wide, next-generation sequencing efforts now underway will provide within the next few years a more comprehensive description of the relations between genome sequence variation and clinical phenotypes.

Meanwhile, new drugs have been added to the armamentarium and new therapeutic strategies are aimed at inducing prompt remission with more intense therapy and prevention of flares with less toxic therapies. There is finally a consensus that what is more important is a strategy aiming at remission and its maintenance with the treatment that best fits the patient. With the approval of the first biologic agent, the disease is finally showing signs of yielding to more targeted therapy and unraveling its heterogeneity and complexity. Most important, it has become clearer than ever that optimal long-term outcome requires not only treatment of the disease flares but also management of comorbidities. To this end, lupus highlights the need for a multidisciplinary approach and superb internal medicine skills.

CHAPTER 82

# Anti-phospholipid Syndrome

Doruk Erkan • Jane E. Salmon • Michael D. Lockshin

**KEY POINTS**

- **Anti-phospholipid antibodies (aPLs) are a family of autoantibodies directed against phospholipid-binding plasma proteins, most commonly β2-glycoprotein 1.**
- **The clinical manifestations range from asymptomatic to arterial/venous thrombosis to catastrophic anti-phospholipid syndrome (APS).**
- **Pregnancy losses typically occur after 10 weeks' gestation (fetal loss), but earlier losses also occur.**
- **Diagnosis should be made in the presence of characteristic clinical manifestations and persistently positive aPLs measured at least 12 weeks apart.**
- **Prevention of secondary thrombosis lacks a risk-stratified approach; the effectiveness of high-intensity anticoagulation is not supported by prospective controlled studies.**
- **A common strategy to prevent fetal loss in aPL-positive patients with a history of pregnancy morbidities is low-dose aspirin and heparin.**
- **Primary thrombosis prevention in persistently aPL-positive persons requires a risk-stratified approach; elimination of reversible thrombosis risk factors and prophylaxis during high-risk periods are crucial. The effectiveness of aspirin is not supported by prospective controlled studies.**
- **Patients with catastrophic APS usually receive a combination of anticoagulation, corticosteroids, intravenous immunoglobulin, and plasma exchange.**

Diagnosis of the anti-phospholipid syndrome (APS) requires that a patient have both a clinical event (thrombosis or pregnancy morbidity) and the persistent presence of the anti-phospholipid antibody (aPL), documented by a solid-phase serum assay (anti-cardiolipin antibody [aCL] or anti–β-2-glycoprotein I antibody [aβ2GPI] IgG or IgM), a coagulation assay (inhibitor of phospholipid-dependent clotting—the lupus anticoagulant test), or both. Preliminary (Sapporo) classification criteria for APS,[1] revised in 2004,[2] are listed in Table 82-1.

Certain factors are not included as criteria but may be helpful in the diagnosis of individual patients. Some of these factors include IgA aCL or aβ2GPI, valvular heart disease, aPL nephropathy, thrombocytopenia, and livedo reticularis (Table 82-2). These factors are rare, nonstandardized, or nonspecific phenomena that are too unreliable for use in clinical studies, but they occur in a sufficient number of patients to support a suspected diagnosis.

APS can occur as an isolated diagnosis (primary APS), or it can be associated with systemic lupus erythematosus (SLE) or another rheumatic disease. Transient aPL positivity, but probably not the syndrome, can be induced by drugs and infection.[3]

## EPIDEMIOLOGY

Low-titer, usually transient, aCL occurs in up to 10% of normal blood donors[4,5]; however, persistent moderate- to high-titer aCL/aβ2GPI or a positive lupus anticoagulant test occurs in less than 1%. The prevalence of positive aPL tests increases with age. Ten percent to 40% of patients with SLE[5] and approximately 20% of patients with rheumatoid arthritis[6] have positive aPL tests; however, the incidence of APS is relatively low.

Based on a limited number of uncontrolled and non–risk-stratified studies, aPL-positive patients who are asymptomatic (i.e., have no history of vascular or pregnancy events) have a 0% to 4% annual risk of thrombosis, whereas patients with other autoimmune diseases such as SLE are at the higher end of the range.[7,8] The aPL profile (low vs. high risk for thrombosis) and patients' clinical characteristics (e.g., the presence or absence of other acquired or genetic thrombosis risk factors) influence the individual risk of thrombosis.[9]

Although determining the frequency of a high-risk aPL profile in general population patients (with no autoimmune diseases) who have aPL-related clinical outcomes is difficult because of a lack of robust data, the best estimates for the overall aPL frequency is 6% for pregnancy morbidity, 14% for stroke, 17% for young age (<50 years), 11% for myocardial infarction, and 10% for deep vein thrombosis.[10,11] Twenty percent of women who have experienced three or more consecutive fetal losses[12] and 14% of patients with recurrent venous thromboembolic disease have aPL.[13]

## ETIOLOGY

The main antigen to which aPLs bind is not a phospholipid but rather a phospholipid-binding plasma protein, namely, β2-glycoprotein 1 (β2-GP1) apolipoprotein H. β2-GP1 is normally present in serum at a concentration of 200 mg/mL, is a member of the complement control protein family, and has five repeating domains and several alleles. An octapeptide in the fifth domain and critical cysteine bonds are necessary for both phospholipid binding and antigenicity[14]; a first-domain site activates platelets.[15,16] In vivo, β2-GP1 binds to phosphatidylserine on activated or apoptotic cell

**TABLE 82-1** Revised Sapporo Classification Criteria for Anti-phospholipid Syndrome

| |
|---|
| **Clinical Criteria** |
| 1. Vascular thrombosis*<br>One or more clinical episodes† of arterial, venous, or small vessel thrombosis‡ in any tissue or organ |
| 2. Pregnancy morbidity<br>(a) One or more unexplained deaths of a morphologically normal fetus at or beyond the 10th week of gestation, *or*<br>(b) One or more premature births of a morphologically normal neonate before the 34th week of gestation because of eclampsia, severe pre-eclampsia, or recognized features of placental insufficiency§, *or*<br>(c) Three or more unexplained consecutive spontaneous abortions before the 10th week of gestation, with maternal anatomic or hormonal abnormalities and paternal and maternal chromosomal causes excluded |
| **Laboratory Criteria** |
| 1. Lupus anticoagulant present in plasma on two or more occasions at least 12 weeks apart, detected according to the guidelines of the International Society on Thrombosis and Hemostasis |
| 2. Anti-cardiolipin antibody of IgG or IgM isotype in serum or plasma, present in medium or high titer (>40 IgG phospholipid [GPL] or IgM phospholipid [MPL], or >99th percentile), on two or more occasions at least 12 weeks apart, measured by a standardized ELISA |
| 3. Anti–β-2-glycoprotein I antibody of IgG or IgM isotype in serum or plasma (in titer >99th percentile) present on two or more occasions at least 12 weeks apart, measured by a standardized ELISA |
| Definite APS is present if at least one of the clinical criteria and one of the laboratory criteria are met. Classification of APS should be avoided if less than 12 weeks or more than 5 years separate the positive anti-phospholipid antibody test and the clinical manifestation. In studies of populations of patients who have more than one type of pregnancy morbidity, investigators are strongly encouraged to stratify groups of subjects according to a, b, or c in this table. |

*Coexisting inherited or acquired factors for thrombosis are not reasons to exclude patients from APS trials. However, two subgroups of patients with APS should be recognized by the presence and absence of additional risk factors for thrombosis. Indicative (but not exhaustive) cases include age (>55 years in men and >65 years in women), the presence of any of the established risk factors for cardiovascular disease (hypertension, diabetes mellitus, elevated low-density lipoprotein or low high-density lipoprotein cholesterol, cigarette smoking, family history of premature cardiovascular disease, body mass index >30 kg/m$^2$, microalbuminuria, and estimated glomerular filtration rate <60 mL/min), inherited thrombophilias, oral contraceptive use, nephritic syndrome, malignancy, immobilization, and surgery. Thus patients who fulfill these criteria should be stratified according to contributing causes of thrombosis.

†A thrombotic episode in the past can be considered a clinical criterion, provided that thrombosis is proved by appropriate diagnostic means and that no alternative diagnosis or cause of thrombosis is found.

‡Superficial venous thrombosis is not included in the clinical criteria.

§Generally accepted features of placental insufficiency include an abnormal or nonreassuring fetal surveillance test (e.g., a nonreactive nonstress test) suggestive of fetal hypoxemia, an abnormal Doppler flow velocimetry waveform analysis suggestive of fetal hypoxemia (e.g., absent end-diastolic flow in the umbilical artery), oligohydramnios (e.g., amniotic fluid index ≤5 cm), or a postnatal birth weight less than the 10th percentile for gestational age.

Investigators are strongly advised to classify patients with APS who are participating in studies into one of the following categories: I, more than one laboratory criteria present (any combination); IIa, only lupus anticoagulant present; IIb, only anti-cardiolipin antibody present; IIc, only anti–β-2-glycoprotein I antibody present.

APS, Anti-phospholipid syndrome; ELISA, enzyme-linked immunosorbent assay.

membranes, including those of trophoblasts, platelets, and endothelial cells. Under physiologic conditions, β2-GP1 may function in the elimination of apoptotic cells[17] and as a natural anticoagulant.[18] Other, less relevant antigens targeted by aPLs are prothrombin, annexin V, protein C, protein S, high- and low-molecular-weight kininogens, tissue plasminogen activator, factor VII, factor XI, factor XII, complement component C4, and complement factor H.[19]

In experimental animal models, passive or active immunization with viral peptides,[20] bacterial peptides,[21] and heterologous β2-GP1[22] induces polyclonal aPLs and clinical events associated with APS. These data suggest that pathologic autoimmune aPL is induced in susceptible humans by infection via molecular mimicry. aPLs are able to upregulate the expression of Toll-like receptor 7 on plasmacytoid dendritic cells, sensitizing these cells to ligand, and thereby perpetuating and amplifying autoimmune responses.[23]

However, infection-induced aPLs (syphilitic and nonsyphilitic *Treponema*, *Borrelia burgdorferi*, human immunodeficiency virus, *Leptospira*, or parasites) are usually β2-GP1 independent and bind phospholipids directly.[24] Drugs (e.g., chlorpromazine, procainamide, quinidine, and phenytoin) and malignancies (e.g., lymphoproliferative disorders) also can induce β2-GP1–independent aPLs. Conversely, autoimmune aPLs bind β2-GP1 or other phospholipid-binding plasma proteins, which in turn bind negatively charged phospholipids such as cardiolipin (β2-GP1–dependent aPLs).

Low levels of aPL may be present normally; one of the functions of normal aPL may be to participate in the physiologic removal of oxidized lipids.

## PATHOGENESIS

Thrombosis is induced by aPLs through multiple mechanisms. Potential pathogenic pathways are illustrated in Figure 82-1. The "two-hit" model of thrombosis associated

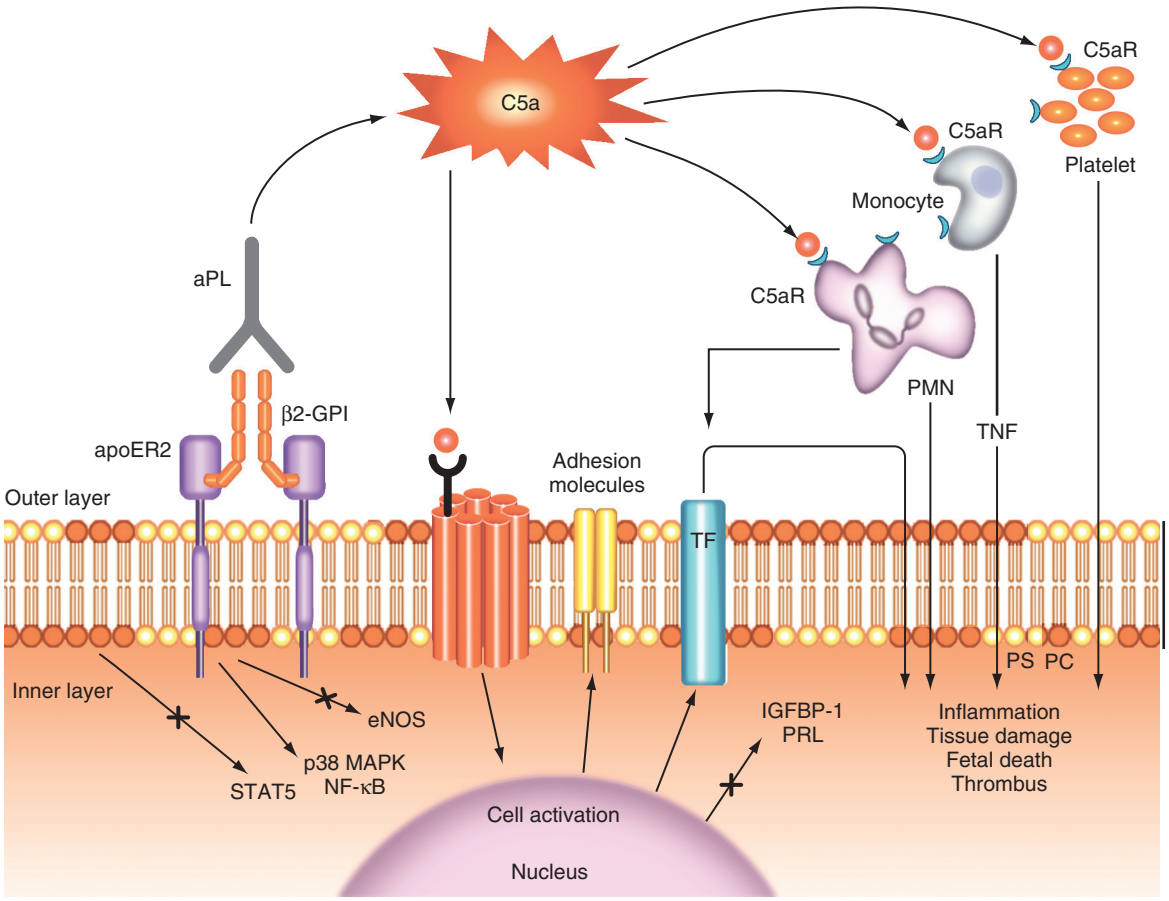

**Figure 82-1** Proposed mechanism of anti-phospholipid antibody (aPL)-related thrombosis and placental injury. The negatively charged phospholipid phosphatidylserine (PS, *yellow circles*) migrates from the inner to the outer cell membrane during activation or apoptosis of platelets and endothelial cells, and it is normally present on trophoblasts. The neutral phospholipid phosphatidylcholine (PC, *red circles*) is the major constituent of the outer layer of inactivated cells. Dimeric β2-glycoprotein 1 (β2-GP1) then binds to PS (probably via β2-GP1 surface receptors such as apoER2′, annexin A2, or a Toll-like receptor), and aPL binds to β2-GP1, activating the classic complement pathway and leading to the generation of C5a, which induces (1) expression of adhesion molecules (e.g., intra-cellular adhesion molecule-1 and tissue factor [TF]), and (2) activation of monocytes, polymorphonuclear (PMN) cells, and platelets, resulting in the release of pro-inflammatory mediators (e.g., TNF and vascular endothelial growth factor receptor-1) and initiation of the proadhesive and prothrombotic state. Cross-linking apoER2′ receptors antagonizes endothelial nitric oxide synthase (eNOS), blocking its phosphorylation and leading to increased leukocyte adhesion and thrombosis. Both nuclear factor-κB (NF-κB) and p38 mitogen-activated protein kinase (p38 MAPK) play a role in the intra-cellular signaling cascade. Anti-phospholipid antibodies also downregulate the expression of trophoblast signal transducer and activator of transcription 5 (STAT5), reducing the endometrial stromal cell production of prolactin (PRL) and insulin growth factor binding protein-1 (IGFBP-1).

with aPL proposes that the initiating "first hit" disrupts the endothelium, and the "second hit" potentiates thrombosis.[25] The process begins with activation or apoptosis of platelets, endothelial cells, or trophoblasts, during which phosphatidylserine (a negatively charged phospholipid) migrates from the inner to the normally electrically neutral outer cell membrane. Circulating β2-GP1 binds to phosphatidylserine, and then aPL binds to a β2-GP1 dimer.[26]

The aPL–β2-GP1 dimer binding activates the complement cascade extra-cellularly; initiates an intra-cellular signaling cascade, probably through the C5a and β2-GP1 surface receptors; and recruits and activates inflammatory effector cells, including monocytes, neutrophils, and platelets, leading to the release of pro-inflammatory products (e.g., TNF, oxidants, and proteases) and the induction of a prothrombotic phenotype.[25-27] The putative receptor of β2-GP1 binding protein that transduces signals from the cell membrane to the nucleus is not yet identified and may vary among cells. The following candidates have been suggested: apoER2 (a member of the low-density lipoprotein receptor superfamily), annexin A2, and a Toll-like receptor.[28-30] Both nuclear factor-κB and p38 mitogen-activated protein kinase play a role in the intra-cellular signaling cascade.[31,32]

In addition, through downregulation of the signal transducer and activator of transcription 5 (STAT5), aPLs inhibit the production of placental prolactin and insulin-like growth factor binding protein-1,[33] and they adversely affect the formation of a trophoblast syncytium, trophoblast migration, invasion, and placental apoptosis—all processes that are required for the normal establishment of placental development.

Other possible contributory mechanisms of aPL-mediated thrombosis include inhibition of coagulation cascade reactions catalyzed by phospholipids (e.g., activation of circulating procoagulant proteins and inhibition of protein C and S activation), oxidative stress, impaired function of

endothelial nitric acid synthase, induction of tissue factor (a physiologic initiator of coagulation) expression and activation on monocytes, reduction of fibrinolysis, and disruption of the annexin V anticoagulant shield.[25]

In experimental animal models, aPLs cause fetal resorption and increase the size and duration of trauma-induced venous and arterial thrombi.[34,35] Inhibiting complement activation prevents experimental aPL-induced fetal death and angiogenic dysregulation–associated abnormal placental development and pre-eclampsia; C5 knockout mice carry pregnancies normally despite having aPLs,[36] implying that a complement-mediated effector mechanism is an absolute requirement for fetal death to occur. Inflammation in association with activation of complement and production of inflammatory mediators such as TNF influence placental development and vascular remodeling.[37] A role for local thrombosis is less clear. Complement activation is also required for experimental thrombosis.[36,38] In addition, aPL-induced reduction of heparin-binding epidermal growth factor–like growth factor leads to defective placentation.[39]

Because high-level aPLs may persist for years in asymptomatic persons, it is likely that vascular injury, endothelial cell activation, or both immediately precede the occurrence of thrombosis in persons bearing the antibody (second-hit hypothesis). Of note, at least 50% of patients with APS who have vascular factors possess other acquired thrombosis risk factors at the time their events occur.[40,41]

Persons congenitally lacking β2-GP1,[42] as well as β2-GP1 knockout mice, appear normal. Although mice lacking β2-GP1 are fertile, the success of early pregnancy is moderately compromised; β2-GP1 is believed necessary for optimal implantation and placental morphogenesis.[43] In certain mouse models of lupus, deletion of β2-GPI potentiates autoimmunity.[44] β2-GP1 polymorphisms influence the generation of aPLs in individuals, but they have only a weak relationship to the occurrence of APS.[45] A cluster of 50 upregulated genes may have an effect on the occurrence of thrombosis in aPL-positive persons.[46]

## CLINICAL FEATURES

Clinical manifestations range from asymptomatic aPL positivity (no history of vascular or pregnancy events) to catastrophic APS (multiple thromboses occurring over days). Thus patients should not be evaluated and managed as if they have a single disease.

### Vascular Occlusion

APS affects all organ systems. Its principal manifestations are venous or arterial thromboses and pregnancy loss (see Table 82-1). Except for their severity, the youth of affected patients, and the unusual anatomic locations (Budd-Chiari syndrome; sagittal sinus and upper extremity thromboses), venous thromboses in APS do not differ clinically from thromboses attributable to other causes. Catastrophic APS can overlap with other thrombotic microangiopathies. Similarly, arterial thromboses differ from non–aPL-associated thromboses only by their recurrent nature, unusual locations, and occurrence in young patients. Deep vein thrombosis and stroke are the most common clinical manifestations of APS. Renal thrombotic microangiopathy, glomerular capillary endothelial cell injury, and thrombosis of renal vessels cause proteinuria without cells in the urine or hypocomplementemia and may lead to severe hypertension, renal failure, or both.[47]

### Pregnancy Morbidity

Pregnancy losses in patients with aPLs typically occur after 10 weeks' gestation (fetal loss), although earlier losses also occur. These pre-embryonic or embryonic pregnancy losses (<10 weeks' gestation) are commonly due to chromosomal and other genetic defects. Pregnancy in women with APS is often normal until the second trimester, when fetal growth slows and amniotic fluid volume decreases. Patients with APS may experience severe, early pre-eclampsia or HELLP (*H*emolysis, *E*levated *L*iver enzymes, *L*ow *P*latelets) syndrome.

In a prospective, multicenter study (PROMISSE), the primary predictor of adverse pregnancy outcome after 12 weeks' gestation in aPL-associated pregnancies was lupus anticoagulant.[48] Prior thrombosis and SLE were also risk factors of adverse pregnancy outcomes. Prior pregnancy loss did not predict outcomes, but previous studies suggested that prior late pregnancy losses predict future losses, independent of the aPL profile.

### Miscellaneous and Noncriteria Manifestations

Many patients have livedo reticularis or thrombocytopenia (Figure 82-2), although these conditions are not specific for APS. The incidence of cardiac valve disease (vegetations, thickening, or both), which is a late manifestation, along with its pathogenesis in persons with APS, are unknown. Recent studies suggest that APS does not add to the risk of atherosclerosis imparted by SLE.[49] Pulmonary hypertension may develop as a result of recurrent pulmonary embolism or small vessel thrombosis; rarely, aPL-positive patients may present with diffuse pulmonary hemorrhage. Some patients experience nonfocal neurologic symptoms such as lack of concentration, forgetfulness, and dizzy spells. Multiple small, hyperintense lesions seen on MRI, primarily in the periventricular white matter, do not correlate well with clinical symptoms. Rarely, high-affinity antiprothrombin

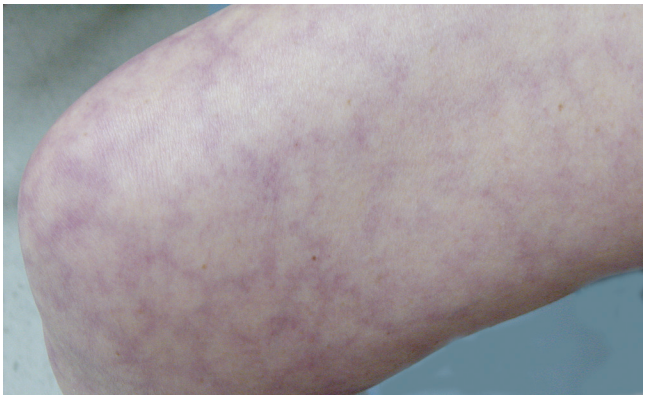

**Figure 82-2** Livedo reticularis in a person with anti-phospholipid syndrome.

antibodies may cause hemorrhage by depleting prothrombin (lupus anticoagulant hypoprothrombinemia syndrome).[50]

### Catastrophic Anti-phospholipid Syndrome

Catastrophic APS is a rare, abrupt, life-threatening complication. It consists of multiple thromboses of medium and small arteries occurring (despite apparently adequate anticoagulation) over a period of days and causing stroke; cardiac, hepatic, adrenal, renal, and intestinal infarction; and peripheral gangrene.[51] In a review of 220 patients with catastrophic APS, the main clinical manifestations included renal involvement in 154 patients (70%), pulmonary involvement in 146 patients (66%), cerebral involvement in 133 patients (60%), cardiac involvement in 115 patients (52%), and cutaneous involvement in 104 patients (47%).[52] Acute adrenal failure may be the initial clinical event. Proposed formal criteria for this syndrome are shown in Table 82-3.[51] Patients often have moderate thrombocytopenia and other features of thrombotic microangiopathies[53]; erythrocytes are less fragmented than in the hemolytic uremic syndrome or thrombotic thrombocytopenic purpura, and fibrin split products are not strikingly elevated. Renal failure and pulmonary hemorrhage may occur. Tissue biopsy specimens show non-inflammatory vascular occlusion.

**TABLE 82-3** Preliminary Criteria for the Classification of Catastrophic Anti-phospholipid Syndrome

| |
|---|
| 1. Evidence of involvement of three or more organs, systems, or tissues* |
| 2. Development of manifestations simultaneously or in less than 1 week |
| 3. Confirmation by histopathology of small vessel occlusion in at least one organ or tissue† |
| 4. Laboratory confirmation of the presence of anti-phospholipid antibody (lupus anticoagulant or anti-cardiolipin or anti–β-2-glycoprotein I antibodies)‡ |
| **Definite Catastrophic APS**<br>All four criteria |
| **Probable Catastrophic APS**<br>Criteria 2 through 4 and two organs, systems, or tissues involved |
| Criteria 1 through 3, except no confirmation 6 weeks apart as a result of the early death of the patient not tested before the catastrophic episode |
| Criteria 1, 2, and 4 |
| Criteria 1, 3, and 4 and development of a third event more than 1 week but less than 1 month after the first, despite anticoagulation |

*Usually, clinical evidence of vessel occlusions, confirmed by imaging techniques when appropriate. Renal involvement is defined by a 50% rise in the serum creatinine level, severe systemic hypertension, proteinuria, or some combination of these.

†For histopathologic confirmation, significant evidence of thrombosis must be present, although vasculitis occasionally may coexist.

‡If the patient has not been diagnosed previously with APS, laboratory confirmation requires that the presence of anti-phospholipid antibody be detected on two or more occasions at least 6 weeks apart (not necessarily at the time of the event), according to proposed preliminary criteria for the classification of APS.

## DIAGNOSIS AND DIAGNOSTIC TESTS

### Laboratory Studies

The diagnosis of APS requires a positive lupus anticoagulant test or a moderate- to high-titer aCL or anti–β2-GP1 IgG or IgM test in patients with characteristic clinical manifestations. Patients with negative lupus anticoagulant tests, aCL, and aβ2GPI should be tested for IgA aCL and aβ2GPI when there is a high suspicion for APS. Positive aPL results require a repeat test after 12 or more weeks to exclude a transient, clinically unimportant antibody. The diagnosis of APS should be questioned if less than 12 weeks or more than 5 years separate the positive aPL test from the clinical manifestation.[2]

The lupus anticoagulant test is a more specific but less sensitive predictor of thromboses than is the anti-cardiolipin test; it correlates better with aPL-related clinical events.[54] Lupus anticoagulant is the strongest aPL test for prediction of pregnancy complications; the predictive power of aCL is due to its association with lupus anticoagulant.[48] However, both false-positive and false-negative lupus anticoagulant test results may occur in patients who have undergone anticoagulation with heparin or warfarin. Documentation of a lupus anticoagulant requires a four-step process: (1) demonstration of a prolonged phospholipid-dependent coagulation screening test, such as activated partial thromboplastin time or dilute Russell viper venom time (however, low-level abnormalities are not clearly linked to APS); (2) failure to correct the prolonged screening test by mixing the patient's plasma with normal platelet-poor plasma, demonstrating the presence of an inhibitor; (3) shortening or correction of the prolonged screening test by the addition of excess phospholipid, demonstrating phospholipid dependency; and (4) exclusion of other inhibitors.[55] Approximately 80% of patients with lupus anticoagulant have anti-cardiolipin, and 20% of patients positive for anti-cardiolipin have lupus anticoagulant.[56]

The aCL enzyme-linked immunosorbent assay (ELISA) is sensitive but not specific for the diagnosis of APS.[57] Although the widely available ELISA test for IgG and IgM aCL is standardized, considerable variability exists among commercial laboratories that perform the test, especially for the IgA isotype.[58] Low-titer aCL or aβ2GPI, transient aPLs, and antibody to noncardiolipin phospholipids (phosphatidylserine and phosphatidylethanolamine) have no or less proven relationship to APS. ELISA tests other than aCL and aβ2GPI are neither standardized nor widely accepted as predictors of clinical illness; they are not part of the Updated APS Classification Criteria.[2]

A false-positive test for syphilis does not fulfill the laboratory criteria, but it should alert physicians to order the aPL tests previously described, especially in patients with a history of aPL-related clinical manifestations.

Whether to test persons with venous occlusive disease or recurrent fetal loss simultaneously for protein C, protein S, and antithrombin III deficiency or for the factor V Leiden and prothrombin mutations is a matter of economics and clinical likelihood; such testing is advisable when feasible. It is useful to test persons with arterial occlusive disease for hyperhomocysteinemia.

Anti-nuclear and anti-DNA antibodies occur in approximately 45% of patients clinically diagnosed as having

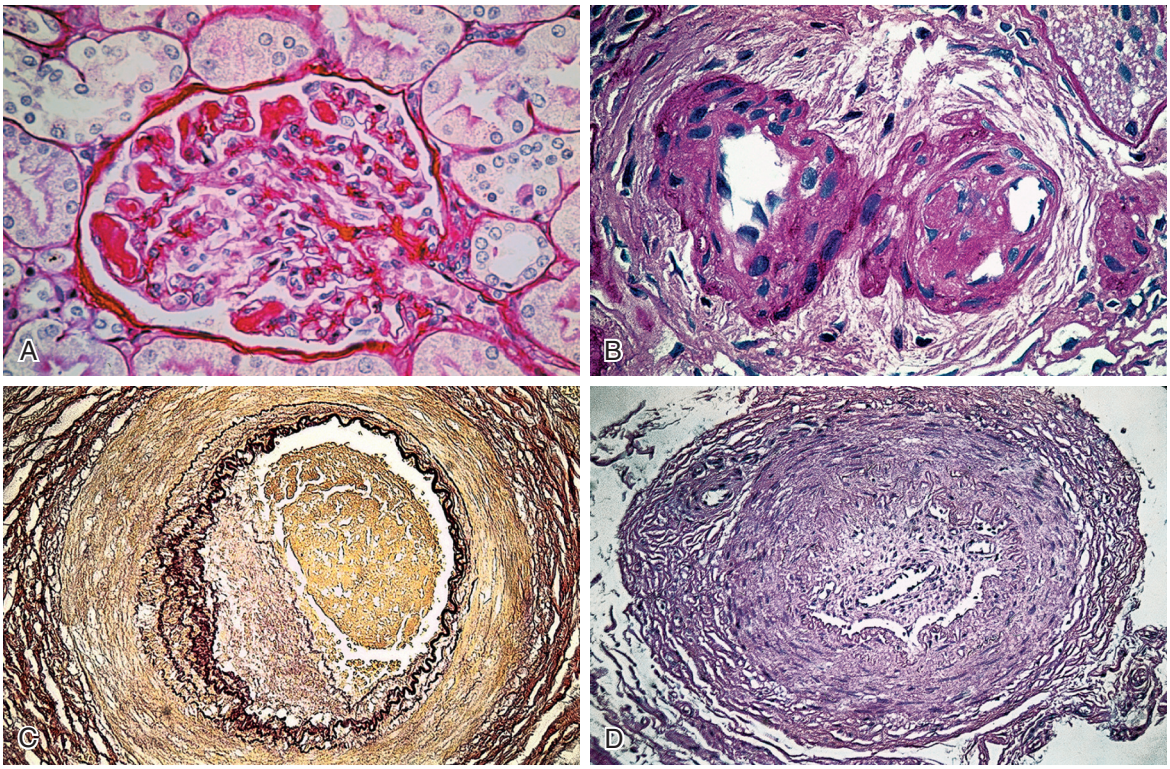

**Figure 82-3** Renal thrombotic microangiopathy in anti-phospholipid syndrome (APS). **A,** A kidney biopsy from a 35-year-old woman with primary APS, microhematuria, and non-nephrotic proteinuria. The glomerulus contains microthrombi and occluding capillary lumina, and endothelial swelling is evident. **B,** The same patient's small renal artery contains organized thrombus, with recanalization and arteriosclerosis (periodic acid–Schiff, ×100). **C,** An autopsy specimen from a 45-year-old man with primary APS. Note the thrombus in various stages of organization, intact elastic lamina with focal reduplication, and medial thickening (elastic Verhoeff stain, ×100). **D,** The same patient's medium-sized peripheral artery. Note the organized thrombus with recanalization, severe fibrointimal thickening, medial hypertrophy, and extreme stenosis of the lumen (hematoxylin and eosin, ×75). *(Courtesy Dr. Surya V. Seshan.)*

primary APS without an accompanying illness[59]; these antibodies do not mandate the additional diagnosis of SLE if the patient has no clinical indicators of SLE. Thrombocytopenia in APS is usually modest (>50,000/mm$^3$); proteinuria and renal insufficiency occur in patients with thrombotic microangiopathy. Pathologic examination demonstrates small artery and glomerular thrombi and recanalization (Figure 82-3). Hypocomplementemia, erythrocyte casts, and pyuria are not characteristic of thrombotic microangiopathy and, when present, imply lupus glomerulonephritis. Erythrocyte sedimentation rate, hemoglobin, and leukocyte count are usually normal in patients with uncomplicated primary APS, except during acute thrombosis. Prothrombin fragment 1 + 2 and other markers of coagulation activation do not predict impending thrombosis.

## Imaging Studies

MRI shows vascular occlusion and infarction consistent with clinical symptoms, with no special characteristics (other than multiple, otherwise unexplained cerebral infarctions in a young person). Multiple small, hyperintense white matter lesions are common and do not unequivocally imply brain infarction. Occlusions usually occur in vessels below the resolution limits of angiography; hence, angiography or magnetic resonance angiography is not indicated unless clinical findings suggest medium- or large-vessel disease. Echocardiography or cardiac MRI may show severe Libman-Sacks endocarditis and intracardiac thrombi.[60]

## Pathology

Skin, renal, and other tissues show thrombotic occlusion of all caliber arteries and veins, acute and chronic endothelial injury and its sequelae, and recanalization in late lesions. Uteroplacental insufficiency was once thought to be due to thrombosis or spiral artery vasculopathy (atherosis, intimal thickening, fibrinoid necrosis, and absence of physiologic changes in the spiral arteries).[61] Consistent with the importance of inflammation in murine models of APS, recent findings demonstrate inflammatory infiltrates, particularly macrophages, and suggest that inflammation contributes to placental injury in patients.[62] The finding of necrotizing vasculitis suggests concomitant lupus or other connective tissue disease. No other diagnostic immunofluorescence or electron microscopic findings have been reported.

## Differential Diagnosis

Infection-induced aCL is usually transient and is more commonly related to IgM than to IgG.[63] Transient aPLs or low-titer aCLs are inconclusive for diagnosis. Research laboratories can distinguish autoimmune from infection-induced aPLs by determining the antibody's β2-GP1

dependence. In a patient who has lupus or lupus-like disease, livedo reticularis, or long-standing thrombocytopenia and who has a persistently positive aPL test in addition to APS-related symptoms, it is usually unnecessary to exclude other diagnoses.

Because the prevalence of aPL-positive ELISA tests increases with age, and because the differential diagnosis of vascular occlusion is broader than it is in young adults, particular care is necessary in diagnosing APS in patients older than 60 years. Sustained high-titer aCL IgG, livedo reticularis, thrombocytopenia, coexisting rheumatic disease, and absence of other causes support a diagnosis of APS.

Heritable deficiency of protein C, protein S, and antithrombin III and the presence of the factor V Leiden (A506G), prothrombin (G20210A), and methylene tetrahydrofolate reductase (MTHFR, C677T) mutations are less common causes of fetal loss.[64] Attribution of pregnancy loss to APS is most certain when no coexisting plausible explanation is known, when the loss occurs after demonstration of a fetal heartbeat (10 weeks), when a significant aPL profile is repeatedly positive before and after pregnancy, and when the placenta shows vasculopathy and infarction. A single pregnancy loss before 10 weeks' gestation in a patient with a low-positive anti-cardiolipin test is more likely to be attributable to fetal chromosomal abnormalities, infection, or maternal hormonal or anatomic abnormalities.

Independent coagulopathies may further increase thrombotic risk in patients with aPLs. These and other acquired thrombotic risk factors (hypertension, diabetes, nephrotic syndrome, venous insufficiency, and immobility) are alternative causes of thromboembolic disease. Arterial occlusion occurs in patients with thrombotic thrombocytopenic purpura, infected or sterile emboli of cardiac or vascular origin, septicemia, hyperhomocysteinemia, myxoma, Takayasu's arteritis, polyarteritis nodosa, and severe Raynaud's disease. The relationship of Sneddon's syndrome (stroke and livedo reticularis, with or without aPLs) to APS is uncertain.

Few conditions mimic or overlap catastrophic APS. Among them are sepsis, disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, hemolytic uremic syndrome, heparin-induced thrombocytopenia, and disseminated embolization from myxoma, atrial thrombus, or atherosclerotic plaque. "Definite" and "probable" catastrophic APS have been defined based on the preliminary classification criteria[51]; however, in a real-world setting, some aPL-positive patients with multiple organ thromboses and/or thrombotic microangiopathies do not fulfill these criteria. Previous APS diagnosis and/or persistent clinically significant aPL positivity is of great importance for catastrophic anti-phospholipid syndrome (CAPS) diagnosis; however, almost half of the patients who experience CAPS do not have a history of aPL positivity.[53] Small vessel occlusions occurring in rapid succession suggest disseminated intravascular coagulation. Severe cerebral and renal disease suggests thrombotic thrombocytopenic purpura, whereas renal failure and hemolysis suggest hemolytic uremic syndrome. Anti-phospholipid antibodies are rarely present in patients with the alternative diagnoses. Acute adrenal insufficiency is highly suggestive of catastrophic APS and Waterhouse-Friderichsen syndrome.

**TABLE 82-4** Treatment Recommendations for Persons Persistently Positive for Anti-phospholipid Antibody

| Clinical Features | Recommendation |
|---|---|
| Asymptomatic | No treatment* |
| Venous thrombosis | Warfarin INR 2.5 indefinitely |
| Arterial thrombosis | Warfarin INR 2.5 indefinitely |
| Recurrent thrombosis | Warfarin INR 3-4 ± low-dose aspirin |
| Pregnancy: | |
| First pregnancy | No treatment† |
| Single pregnancy loss at <10 wk | No treatment† |
| ≥1 Fetal or ≥3 (pre)-embryonic losses, no thrombosis | Prophylactic heparin‡ + low-dose aspirin throughout pregnancy, discontinue 6-12 wk postpartum |
| Thrombosis regardless of pregnancy history | Therapeutic heparin§ or low-dose aspirin throughout pregnancy, warfarin postpartum |
| Valve nodules or deformity | No known effective treatment; full anticoagulation if emboli or intracardiac thrombi demonstrated |
| Thrombocytopenia >50,000/mm$^3$ | No treatment |
| Thrombocytopenia <50,000/mm$^3$ | Prednisone, IVIG |
| Catastrophic anti-phospholipid syndrome | Anticoagulation + corticosteroids + IVIG or plasmapheresis |

*Aspirin (81 mg/day) may be considered in high-risk patients with multiple non-aPL cardiovascular risk factors.
†Aspirin (81 mg/day) may be considered.

§Enoxaparin 1 mg/kg subcutaneously twice daily or 1.5 mg/kg subcutaneously once daily.
INR, International normalized ratio; IVIG, intravenous immunoglobulin.

## TREATMENT

### Thrombosis

Treatment recommendations are summarized in Table 82-4. Anticoagulation with heparin is the treatment for acute thrombosis in patients with APS. Warfarin, occasionally in association with low-dose aspirin, is used for secondary thrombosis prophylaxis. Two randomized, controlled trials demonstrated that moderate doses of warfarin (international normalized ratio [INR], 2 to 3) and high-intensity warfarin (INR, 3 to 4) are equally protective against recurrence in patients with APS after the first thrombosis.[65,66] The intensity of anticoagulation for aPL-related arterial thrombosis is still a matter for debate because in both studies, patients with arterial events constituted less than half of the study population. Although patients with APS who have arterial thrombosis and who are at high risk for recurrence may require high-intensity anticoagulation, in the absence of risk-stratified studies, *high risk* has no consensus definition and currently is based solely on clinical judgment.

Aspirin is the standard of care after an ischemic stroke or a transient ischemic attack to prevent a recurrence in aPL-negative patients. Although most aPL-positive patients

with ischemic strokes receive warfarin, the Antiphospholipid Antibody in Stroke Study (APASS) concluded that for selected aPL-positive patients who do not have atrial fibrillation or high-grade stenosis, aspirin and warfarin (target INR, 2.2) are equivalent in terms of both efficacy and major bleeding complications.[67] The APASS results probably do not apply to conventionally defined APS because the average age of study participants was much higher than that of the average APS population; in addition, the aPL determination was performed only once at study entry, and the titer cutoff for assigning a patient to the positive aCL group was very low. However, aspirin is an option for older aPL-positive patients who have a single low-titer anti-cardiolipin test and who have only had one stroke.

Some patients require larger than expected doses of both heparin and warfarin to achieve therapeutic anticoagulation. Uncommonly, positive lupus anticoagulant tests cause the INR to be unreliable.[68] Patients with constantly fluctuating INR levels and/or recurrent events despite therapeutic INR may be monitored by the measurement of anti–factor Xa activity or another appropriate assay.

For well-anticoagulated patients who continue to have thromboses, the addition of aspirin (81 to 325 mg/day) can be considered. Experimental evidence (with in vitro and/or animal models) and clinical evidence (in lupus patients) suggest that hydroxychloroquine may decrease the incidence of thrombosis; similarly, experimental evidence indicates that statins can interfere with aPL-mediated thrombosis.[69] Controlled studies are needed to determine the effectiveness of hydroxychloroquine and statins in patients with APS. Corticosteroids have no established role in the treatment of APS but are used for rheumatic symptoms in patients with accompanying systemic autoimmune illness. However, high doses of corticosteroids usually are given empirically to patients who have severe thrombocytopenia, hemolytic anemia, and catastrophic APS.

No controlled studies in patients with APS have been published for clopidogrel, pentoxifylline, aspirin-dipyridamole, argatroban, hirudin, and other new anticoagulant agents. Given lack of data, a recent Task Force on APS Treatment Trends recommended that oral direct thrombin or anti–Factor Xa inhibitors can be considered in patients with APC who have a first venous thrombosis only when there is known vitamin K antagonist allergy/intolerance or poor anticoagulant control. No data recommend use of these new agents in patients with APS who have recurrent venous thrombosis while undergoing therapeutic anticoagulation or who have APS-related arterial thrombosis.[70] Neither hirudin nor fondaparinux inactivates complement, and neither drug protects mice with experimental APS against pregnancy loss, so they may not be effective in human disease. Clinical experience suggests that thrombolytic agents for acute thrombosis are not helpful because reocclusion occurs rapidly.

Currently available data, although retrospective and not risk stratified, indicate that lifelong anticoagulation of patients with APS who have had vascular events is appropriate.[71] However, given recent recognition that many thrombotic events have recognizable triggers, a Task Force on Prevention and Management of Thrombosis recommended that in cases of a first venous event, a low-risk aPL profile, and a known transient precipitating factor, anticoagulation could be limited to 3 to 6 months.[72]

## Pregnancy Morbidity

Heparin is indicated at the diagnosis of pregnancy in an aPL-positive woman who has had prior pregnancy losses attributable to APS. Because warfarin is teratogenic, only unfractionated or low-molecular-weight heparin is used for the treatment of affected pregnancies in the United States; in other countries, converting to warfarin after the first trimester may be considered acceptable.[73] Low-molecular-weight heparin is the treatment of choice because of the decreased risk of thrombocytopenia and osteoporosis.

Patients with prior fetal losses at later than 10 gestational weeks should be treated with prophylactic heparin (enoxaparin, 30 to 40 mg subcutaneously once daily), together with low-dose aspirin; this regimen increases the fetal survival rate from 50% (untreated) to 80%.[74,75] Women who have had prior thromboses must undergo full anticoagulation (enoxaparin, 1 mg/kg subcutaneously twice daily or 1.5 mg/kg subcutaneously once daily) throughout pregnancy because the risk of new thrombosis markedly increases both during pregnancy and during the postpartum period. Even with treatment, prematurity and fetal growth restriction may occur. Clopidogrel and newer anti-thrombotic agents have not been cleared for use in pregnancy. Intravenous immunoglobulin (IVIG) and hydroxychloroquine can be considered in patients who do not respond to heparin treatment.

In aPL-positive women with prior thrombosis, warfarin is changed to heparin or low-molecular-weight heparin before conception, if possible, or at the first missed menstrual period. In aPL-positive women without prior thrombosis, if heparin is indicated during pregnancy, treatment begins after confirmation of pregnancy, continues until 48 hours before anticipated delivery (to allow epidural anesthesia), and resumes for 8 to 12 weeks during the postpartum period. Some physicians recommend the initiation of heparin before conception; no clinical trial supports this recommendation, however, and the risk associated with longer-duration heparin therapy is considerable. Patients in most published series received both low-dose aspirin and heparin, but the benefit of adding aspirin is unknown.

Because of the risk of postpartum thrombosis, it is prudent to continue anticoagulation for 8 to 12 weeks during the postpartum period and then discontinue it by tapering the doses. If desired, conversion from heparin to warfarin may be accomplished after the first or second postpartum week. Breastfeeding is permissible with both heparin and warfarin.

No studies unequivocally justify the treatment of women with aPLs during a first pregnancy, women with only very early losses, or women whose aPL titers are low or transient. Nonetheless, it is common to offer such patients low-dose aspirin.

## Asymptomatic Anti-phospholipid Antibody–Positive Persons

The persistence of aPLs for decades without occurrence of clinical events is well documented. The probability that the

syndrome will eventually develop in an asymptomatic person who is incidentally found to have aPLs is likely low.[7] Anticoagulation is not indicated for the prophylactic treatment of asymptomatic aPL-positive persons. For persons with moderate- to high-titer persistent aPLs, education about the meaning of abnormal tests is appropriate, as is a discussion of warning signs to be reported. Elimination of reversible thrombosis risk factors and prophylaxis during high-risk periods, such as surgical procedures, are crucial.

A recent meta-analysis demonstrated that the risk of first thrombosis is decreased by administration of low-dose aspirin among asymptomatic persons with aPL and patients with SLE or obstetrical APS; however, no significant risk reduction was observed when considering only prospective studies or those with the best methodologic quality.[76] In the only randomized, double-blind, placebo-controlled trial, low-dose aspirin (81 mg) appeared to be no better than placebo in preventing first thrombotic episodes in persistently asymptomatic aPL-positive patients; the incidence rate of first thrombosis was relatively low.[9]

Although drugs that induce lupus (e.g., hydralazine and phenytoin) may also induce aPLs, they may be prescribed for patients with aPLs if no alternatives are available. Drugs that promote thrombosis (e.g., estrogen and oral contraceptives that contain estrogen) are not currently deemed safe, even for asymptomatic women serendipitously known to have high-titer antibodies. This advice does not translate to a recommendation to test all healthy women before prescribing such medications, but it does suggest that special attention and further evaluation should be provided to persons with family histories or clinical suggestions of rheumatic disease, livedo reticularis, biologic false-positive tests for syphilis, or borderline thrombocytopenia. No reliable information is available regarding the safety of progestin-only contraception, "morning after" contraception, or the use of raloxifene, bromocriptine, or leuprolide in patients with APS. A small retrospective review of women undergoing artificial reproductive technology (in vitro fertilization) procedures demonstrated no thrombotic events.[77]

### Anti-phospholipid Antibody–Positive Persons with Ambiguous or Noncriteria Events

Some patients with positive aPL tests have clinical events of ambiguous meaning (e.g., dizzy or confusional episodes, nonspecific visual disturbances, and very early pregnancy loss). No consensus has been reached regarding the treatment of such persons. Because full anticoagulation carries high risk, many physicians prescribe low-dose (81 mg) aspirin, hydroxychloroquine, or both daily. No published data support or repudiate this recommendation.

Based on the presumed pathogenesis, some physicians prescribe anticoagulation for patients with noncriteria manifestations of aPL such as livedo reticularis, thrombocytopenia, leg ulcers, thrombotic microangiopathy, or valvulopathy. The efficacy of anticoagulation is not known in these conditions. One small, descriptive, cross-sectional study provides evidence that B cell depletion with rituximab is well tolerated and can be effective for refractory thrombocytopenia and skin ulcers in aPL-positive patients.[78] An open-label phase IIa descriptive pilot study assessing the effectiveness and safety of rituximab in patients with noncriteria and/or anticoagulation-resistant manifestations of aPL demonstrated that rituximab, even without inducing substantial change in aPL profiles, may be effective in controlling some noncriteria manifestations of aPL.[79]

### Catastrophic Anti-phospholipid Syndrome

The onset of catastrophic APS is usually sudden and immediately life threatening. Early diagnosis can be a challenge, especially in patients with no history of APS. However, early diagnosis is critical because, in contrast to other causes of multiple organ dysfunction syndrome, appropriate therapy includes anticoagulation and corticosteroids in combination with repeated plasma exchange, IVIG, and, in desperate situations, other modalities such as cyclophosphamide or rituximab. A case report described improvement of post–kidney transplant thrombotic microangiopathy in a patient with APS who was treated with eculizumab (terminal complement inhibitor).[80] In another patient with catastrophic APS who was resistant to anticoagulation, immunosuppression, plasmapheresis, and rituximab, eculizumab successfully blocked complement activity, aborted progressive thrombosis, and reversed thrombocytopenia.[81]

### Anti-phospholipid Antibody–Negative Persons with a Clinical Event

In patients clinically suspected of having APS but who have normal findings of aCL, lupus anticoagulant, and anti-β2-GP1 tests, alternative causes of clotting must be sought. Even among patients with concomitant rheumatic disease, APS may not be the cause of recurrent thromboembolism or pregnancy loss. Patients with SLE experience emboli from SLE-related cardiac valvular disease, vasculitis, or atheroma. Other patients have factor V Leiden or some other procoagulant mutation. Recurrent pregnancy losses may be caused by chromosomal abnormalities, uterine infection, diabetes, hypertension, or non-aPL coagulopathy. The concept of "seronegative" APS is extremely controversial.

## OUTCOME

Pulmonary hypertension, neurologic involvement, myocardial ischemia, nephropathy, gangrene of extremities, and catastrophic APS are associated with a worse prognosis. During long-term follow-up, serious morbidity and disability occur in an unpredictable proportion of patients with primary APS who experience major vascular events and in those who have delays in diagnosis and treatment. Thus the long-term functional outcome of patients with primary APS is poor; at 10 years, permanent organ damage develops in one third of patients, and one fifth are unable to perform everyday activities.[82]

Long-term outcomes of children born of women with APS are not known. In many patients with long-standing APS, the development of severe cardiac valvular disease necessitates valve replacement, and rare patients experience renal failure as a result of thrombotic microangiopathy. Immediate thrombosis may cause loss of a transplanted kidney or other organ; aPL positivity correlates with poor graft survival after renal transplantation in patients with SLE.[83]

Serious perioperative complications may occur despite prophylaxis in aPL-positive patients because they are at additional risk for thrombosis when undergoing surgical procedures. Thus perioperative strategies should be clearly identified before any surgical procedure is performed. In addition, pharmacologic and physical antithrombosis interventions should be vigorously employed, periods without anticoagulation should be kept to an absolute minimum, intravascular manipulation for access and monitoring should be minimized, and any deviation from a normal course should be considered a potential disease-related event.[84]

PART 12 SCLERODERMA, INFLAMMATORY MYOPATHIES, AND OVERLAP SYNDROMES

CHAPTER 83

# Etiology and Pathogenesis of Scleroderma

John Varga

**KEY POINTS**

- Scleroderma/systemic sclerosis (SSc) has a complex pathogenesis and protean clinical manifestations that reflect the underlying early immune dysregulation and microangiopathy, and subsequent systemic fibrosis.
- Marked patient-to-patient variability exists in clinical and laboratory manifestations, disease course, and molecular signatures, suggesting the existence of distinct disease subsets.
- Vascular lesions in small blood vessels occur early and progress to obliterative vasculopathy that causes tissue hypoxia, oxidative stress, and vascular complications.
- Immune dysregulation manifested by autoantibodies, evidence of innate immune activation, and an "interferon signature" is prominent in SSc, but its role as a primary factor in pathogenesis has not been established.
- Genetic association studies implicate the human leukocyte antigen (HLA) and other immunoregulatory genes that are also associated with systemic lupus erythematosus.
- Fibrosis is associated with sustained mesenchymal cell activation by growth factors, cytokines, chemokines, hypoxia and reactive oxygen species, and aberrant reactivation of developmental pathways.

Scleroderma or systemic sclerosis (SSc) is an uncommon disease of unknown cause and complex pathogenesis. The hallmarks of SSc are (1) autoimmunity, (2) inflammation, (3) functional and structural alterations in small blood vessels, and (4) widespread interstitial and vascular fibrosis affecting the skin and internal organs. This unique constellation of distinct but related pathophysiologic features, illustrated in Figure 83-1, accounts for the characteristic clinical manifestations of SSc. In its early stage, SSc may be dominated by clinical manifestations reflecting inflammation and vascular injury; in advanced stages of SSc, fibrosis and vascular insufficiency underlie the prominent clinical manifestations. However, there is enormous patient-to-patient variability in the presence, severity, and progression of these features. Recent advances in cell and molecular biology, mouse genetic engineering, genetics, and functional genomics have identified a large number of molecules, signaling pathways, and cell types implicated in the pathogenesis of SSc. The following sequence represents a plausible view of SSc pathogenesis: environmental triggers and epigenetic modifications in a genetically susceptible individual set off a cascade of events with early vascular injury, immune cell activation, autoimmunity, oxidative stress, and mesenchymal cell activation, resulting in excessive matrix accumulation and progressive tissue damage. Over time, chronic vascular insufficiency and widespread fibrosis cause failure of vital organs, accounting for substantial morbidity and mortality.

## ETIOLOGY

Neither the cause of SSc nor the precise contribution of genetic susceptibility is fully understood. Evidence indicates that infectious agents, environmental toxins, and drugs, as well as microchimerism, might be potential triggers.

### Genetic Risk: Family Studies

Familial clustering of a disease is considered to be evidence of inherited disease susceptibility, but such clustering might be explained by shared environmental exposures, shared genetic background, or the interaction between genes and environment.[1] The risk of SSc is considerably increased among first-degree relatives of persons with SSc compared with the general population. In one study, the relative risk of SSc among first-degree relatives of persons with SSc was 13, thus identifying a family history as the strongest known risk factor for SSc.[2] In a twin study of SSc only a relatively small disease concordance rate (4.7%) was found, although concordance for anti-nuclear antibody positivity was 90% for monozygotic (identical) twins and 40% for dizygotic (fraternal) twins.[3] Raynaud's disease and pulmonary fibrosis show increased prevalence in pedigrees of patients with SSc.[4] Moreover, up to 36% of first-degree family members of patients with SSc have autoimmune conditions, with the most common being hypothyroidism, hyperthyroidism, rheumatoid arthritis, and systemic lupus erythematosus (SLE).

### Genetic Association Studies

Genetic association studies using candidate gene approaches and, more recently, genome-wide association (GWA) studies have been performed in large multinational patient

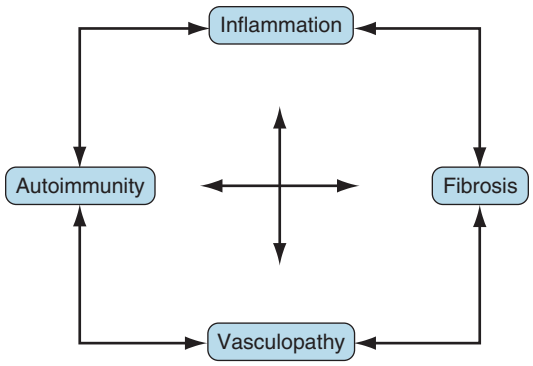

**Figure 83-1** The pathophysiologic quartet underlying systemic sclerosis. Patients with systemic sclerosis display evidence of inflammation, autoimmunity, vasculopathy, and fibrosis. Autoimmunity and vasculopathy generally precede the onset and contribute to the progression of fibrosis. Vascular obliteration and interstitial fibrosis perpetuate and further exacerbate chronic autoimmunity and inflammation. *(Courtesy Kathleen Kelley.)*

cohorts. The major histocompatibility complex is the dominant genetic region implicated in autoimmune disease, including SSc. The interpretation of human leukocyte antigen (HLA) associations is complicated by the extensive linkage disequilibrium of risk haplotypes. It has long been known that specific HLA alleles are associated with SSc and specific autoantibodies. For instance, a case-control study revealed strong associations with HLA DRB1*1104, DQA1*0501, and DQB1*0301 haplotypes.[5] Candidate gene approaches typically look for single nucleotide polymorphisms [SNPs]), the most common form of DNA variation. Non-HLA susceptibility loci associated with SSc include the protein tyrosine phosphatase nonreceptor 22 (PTPN22), which has been associated with SLE, myasthenia gravis, vitiligo, and Addison's disease; IL-1β and NLRP1, an inflammasome scaffold that promotes pro-IL-1β maturation and processing; and interferon regulatory factor 5 (IRF5), a transcription factor that mediates type I interferon (IFN) induction and is associated with SLE, as well as SSc and interstitial lung disease. The association of IRF5 with SSc is particularly interesting in light of the role of IFN type I in immune responses. Table 83-1 summarizes SSc susceptibility genes identified to date, although there will undoubtedly be many more discovered. In addition to classic SNPs, informative genetic polymorphisms in SSc also include copy number variations, rare allelic variants, and epigenetic changes.

## Other Candidate Genes and Genome-wide Association Studies

Thus far, candidate gene approaches focusing on genes involved in vascular homeostasis or extra-cellular matrix (ECM) remodeling have not yielded robust associations with SSc. Several GWA studies in large and ethnically diverse populations are currently under way. These unbiased approaches have an advantage over candidate gene studies in that they are driven by discovery rather than *a priori* hypotheses. The first large-scale SSc GWA study analyzed 300,000 SNPs in a cohort of 2296 cases and 5014 healthy control subjects.[6] Statistically significant associations were found with SNPs in the HLA region, as well as with *IRF5*, *TNFAIP3*, and *CD247*, a gene implicated in T cell signaling and also associated with susceptibility to SLE. The results of genetic association studies to date can be summarized as follows: (1) Genetic variants associated with SSc susceptibility are involved in innate and adaptive immune responses, and (2) they are largely shared with SLE and other autoimmune diseases. It is worth noting that important associations can be missed by GWA studies using current technologies. Moreover, despite the wealth of emerging information, the genetic associations discovered to date are of relatively modest magnitude, with odds ratios that are generally less than 1.5. This finding points to the potential importance of gene-gene interactions (epistasis), particularly for genes within the same molecular pathways. Even more important are the contributions of gene-environment interactions. A current challenge in SSc research is to delineate how genes shared among diverse autoimmune conditions contribute to disease-specific phenotypes. Shedding light on this important problem will require large collaborative studies involving phenotypically well-characterized populations of varied ethnic background and meta-analyses.

**TABLE 83-1** Selected Systemic Sclerosis Susceptibility Genes

| Locus | Chromosome | Associated SSc Subset | Potential Pathogenic Mechanism |
|---|---|---|---|
| *HLA* | 6 | Various | Antigen presentation |
| *PTPN22* | 1p3.2 | Topo1$^+$ positive | T and B cell activation |
| *NLRP1* | 17p13.2 | dcSSc, pulmonary fibrosis | Inflammasome component, IL-1β processing |
| *IRF5* | 7q32 | dcSSc | Transcription factor required for induction of type I interferon |
| *STAT4* | 2q32.3 | lcSSc, ACA | Transcription factor for IL-12 and IL-23 |
| *BANK1* | 4q24 | dcSSc | Scaffolding protein involved in B cell signaling |
| *TNFSF4* | 1q25 | SSc | T cell co-stimulation |
| *T-bet* | 17.q21.32 | SSc | Transcription factor for Th1 T cell polarization |

Based on published candidate gene studies and genome-wide association studies as of 2015.

ACA, Anti-centromere antibody; dcSSc, diffuse cutaneous SSc; lcSSc, limited cutaneous SSc; SSc, systemic sclerosis; Th1, T helper 1.

## Epigenetic Factors

The relatively modest contribution of genetic factors to disease susceptibility in SSc has drawn attention to the role of epigenetic modifications in pathogenesis. Epigenetic modifications, often induced by environmental exposures, can alter gene expression without changes in the genetic code (see Chapter 22). Three key forms of epigenetic

modifications are DNA methylation, histone modifications, and expression of noncoding (long and micro) RNAs.

A genome-wide DNA methylation analysis in SSc revealed a large number of differentially methylated cytosine-phosphatidyl-guanine (CpG) sites in SSc fibroblasts.[7] Pathway analysis of genes that were abnormally methylated in SSc implicated genes involved with ECM-receptor interaction and focal adhesion. Another recent study using a candidate gene approach demonstrated that the antifibrotic transcription Friend leukemia integration 1 (Fli1) is repressed at the epigenetic level in explanted SSc fibroblasts because of promoter methylation, resulting in gene silencing.[8] Other reports evaluating SSc T cells showed a generalized reduction of DNA methylation and of methylation-regulating genes such as *DNMT1*, as well as increased DNA methylation of FOXP3, the transcription factor controlling regulatory T cell (Treg) differentiation. Moreover, SSc fibroblasts showed elevated levels of methylation-regulating genes and global DNA hypermethylation, accompanied by transcriptional silencing of genes involved in negative regulators of Wnt signaling such as DKK1, WIF, and SFRP1.[9-11]

Post-translational modifications of nucleosome histones, including acetylation/deacetylation and methylation, also can profoundly influence gene expression and have been implicated in SSc. For instance, the levels of the acetyltransferase p300 are elevated in SSc fibroblasts, and p300 promotes fibrotic responses by enhancing stimulation of collagen gene transcription.[12]

MicroRNAs (miRNAs) are a large family of 18 to 23 nucleotide noncoding RNAs that function as intra-cellular regulators of gene expression. Of particular interest are miR-21 and miR-29, which are aberrantly expressed in SSc. miR-21, which is elevated in SSc fibroblasts, suppresses expression of antifibrotic Smad7, thereby promoting expression of profibrotic genes.[13] In contrast, miR-29, which is reduced in SSc fibroblasts and is suppressed by fibrotic stimuli, has inhibitory effects on fibrotic gene expression.[14,15] miRNAs also can be detected in the circulation and exert biologic activities when they are incorporated into microvesicles. Although the full spectrum and mechanism of action of miRNAs that are aberrantly regulated in SSc remain to be investigated, these noncoding regulatory RNAs may serve as both biomarkers and therapeutic targets in SSc.

## INFECTIOUS AGENTS AND VIRUSES

Along with exposure to certain environmental and occupational agents and drugs, viruses such as Epstein-Barr virus (EBV), human cytomegalovirus (hCMV), and parvovirus B19 have been implicated in SSc. Patients with SSc have anti-hCMV antibodies directed against the UL83 and UL94 protein epitopes on hCMV. Anti-UL94 antibodies can induce endothelial cell apoptosis and fibroblast activation, suggesting a direct role for anti-viral antibodies in tissue damage. Antitopoisomerase-I can cross-react with hCMV-derived proteins, implicating molecular mimicry as a mechanism linking hCMV infection and SSc.[16] CMV is implicated in the pathogenesis of allograft vasculopathy, a complication of organ transplantation characterized by vascular neointima formation and smooth muscle cell proliferation strikingly reminiscent of the obliterative proliferative vasculopathy seen in SSc. In dermal fibroblasts, hCMV stimulates synthesis of the profibrotic growth factors in vitro.[17] In a recent study, genetic material from EBV were identified within dermal fibroblasts and microvessels in the skin of patients with SSc. Moreover, EBV induces Toll-like receptor (TLR)-mediated cellular responses in SSc fibroblasts, suggesting a potential role for EBV reactivation in vascular injury and fibrosis in SSc.

## ENVIRONMENTAL EXPOSURES, DIETARY SUPPLEMENTS, DRUGS, AND RADIATION

Although reports of putative geographic clustering suggest a role for shared environmental exposures, careful investigations have generally failed to substantiate apparent clusters of SSc. On the other hand, well-documented epidemic outbreaks of SSc-like illnesses with acute onset and chronic course have been reported. One such illness, called the *toxic oil syndrome*, was linked to the ingestion of contaminated rapeseed cooking oils.[18] Dietary supplements containing L-tryptophan were implicated in an explosive outbreak of the eosinophilia-myalgia syndrome (EMS) in 1989.[19] The EMS epidemic subsided after the ban on L-tryptophan, but sporadic cases of EMS following the ingestion of L-tryptophan and other food supplements continue to be reported. Although scleroderma-like skin and organ fibrosis was a prominent manifestation of these apparently de novo toxicoepidemic syndromes, the associated clinical, histopathologic, and laboratory features clearly differentiate them from SSc.[20]

The frequency of SSc appears to be increased among men with occupational exposure to silica dust. This observation was recently confirmed by a meta-analysis of 16 observational studies, with risk estimates as high as 15.[21] Other environmental exposures occasionally linked with SSc include polyvinyl chloride, toluene, xylene, trichloroethylene, and organic solvents. Additional reports alleged an association between SSc and environmental exposures to pesticides, hair dyes, and industrial fumes. Although exposure to cigarette smoke is known to increase the risk of multiple autoimmune diseases, no evidence to date implicates it as a risk factor for SSc.

Certain drugs have been implicated in SSc-like illnesses. The best studied is the anticancer drug bleomycin, which induces skin and lung fibrosis in the mouse (discussed in a subsequent section). Other drugs potentially implicated include pentazocine, docetaxel and paclitaxel, and cocaine. The use of appetite suppressants has been linked to the development of pulmonary arterial hypertension (PAH). The occurrence of SSc in women after cosmetic breast augmentation with silicone implants raised significant concern regarding a possible causal association.[22] Subsequent large-scale epidemiologic surveys and a meta-analysis, however, failed to confirm an increased risk of SSc or of other connective tissue diseases among women with silicone breast implants.[23] Radiation treatment for malignant neoplasms has been linked with the onset of de novo SSc, as well as exacerbation of tissue fibrosis in patients with pre-existing SSc.[24] Some of the environmental agents and drugs that have been linked with the development of SSc are listed in Table 83-2.

## MICROCHIMERISM

Healthy women may harbor circulating, and occasionally tissue-resident, stem cells of fetal origin that persist for many years after pregnancy, a condition called *microchimerism*. In some studies it was found that the number of circulating fetal cells is elevated in women with SSc compared with healthy women.[25] The persistence of fetal cells in women with SSc might be linked to the development of the disease through a graft-versus-host–like response triggered by the fetal cells or through a maternal (auto)immune response against the fetal cells.

## PATHOLOGY

### General Features

The pathologic hallmarks of SSc are a non-inflammatory proliferative/obliterative vasculopathy affecting small arteries and arterioles in multiple vascular beds, loss of capillaries (rarefication), and fibrosis that is most prominent in the skin, lungs, and heart.[26] Inflammatory cell accumulation is generally absent in long-standing SSc but may be prominent in patients with early-stage disease. Infiltrates are located predominantly around blood vessels and are composed primarily of $CD4^+$ T lymphocytes, dendritic cells (DCs), and monocytes/macrophages.

### Vascular Pathology

Vascular injury and activation are the earliest and possibly primary events in the pathogenesis of SSc. Histopathologic evidence of vascular damage can be detected in involved and uninvolved skin and is present before fibrosis.[27] Raynaud's phenomenon typically precedes other manifestations of SSc. Additional clinical signs indicative of vasculopathy include mucocutaneous telangiectasia; nailfold capillary changes (giant capillaries, hemorrhages, and avascular areas); PAH; digital tip pitting and ischemic ulcers; gastric antral vascular ectasia (also called *watermelon stomach*); and scleroderma renal crisis.

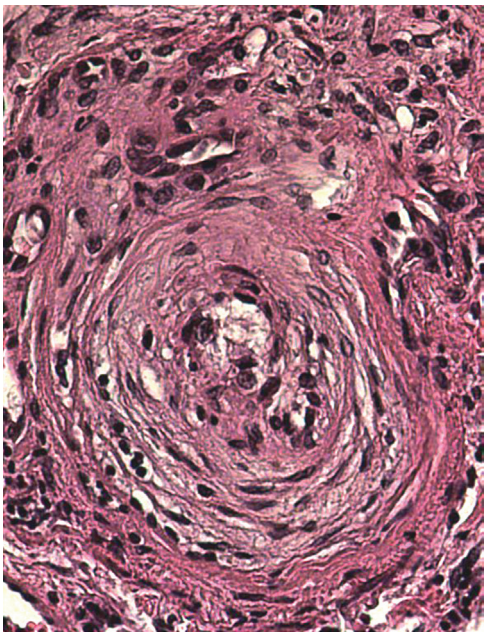

**Figure 83-2** Histologic appearance of systemic sclerosis vasculopathy. A pulmonary arteriole showing extensive medial hypertrophy and intimal thickening, leading to narrowing of the vascular lumen.

The most characteristic histopathologic finding in the small and medium-sized arteries is bland intimal proliferation (Figure 83-2). Intimal hypertrophy, a finding that SSc shares with chronic allograft arteriopathy, is thought to result from proliferation and migration of myointimal cells and local accumulation of collagen and other ECM components.[28] The vascular basement membranes are thickened and reduplicated. These changes are most prominent in the heart, lungs, kidneys, and gastrointestinal tract. A systematic survey of SSc skin biopsies revealed a marked reduction in the number of capillaries (rarefaction) and loss of vascular endothelial cadherin, a molecule required for vascular tube formation.[29] Remarkably, this study showed that clinical improvement after high-dose immunosuppressive therapy was accompanied by capillary regeneration in the skin.

Impaired fibrinolysis, increased levels of von Willebrand factor, and ongoing platelet aggregation are prominent and contribute to a procoagulant milieu. Endothelial cell injury itself causes further platelet aggregation, release of platelet-derived growth factor (PDGF) and endothelin-1 (ET-1), and endothelial cell apoptosis.[30] Vasculitic lesions and immune complex deposition in the vessel walls are uncommon. In later stages of SSc, extensive fibrin deposition and perivascular fibrosis cause progressive luminal occlusion, and eventually there is a striking paucity of small blood vessels and capillaries in lesional tissue.[31] Loss of vascular supply leads to chronic tissue hypoxia, which directly contributes to fibrosis. Widespread proliferative/obliterative vasculopathy of small and medium-sized arteries and capillary rarefaction are the pathologic hallmarks of all forms of SSc. In patients with SSc-associated PAH, pulmonary arteriolar intimal proliferation and evidence of veno-occlusive disease are prominent. In contrast to idiopathic PAH, plexogenic arteriopathy is uncommon in SSc-associated PAH.[32]

### Tissue Fibrosis

Fibrosis is characterized by excessive accumulation of fibrillar collagens, fibronectin, elastin, proteoglycans, cartilage oligomeric matrix protein, and other structural components of the ECM. Matrix deposition causes disruption and, ultimately, complete obliteration of tissue architecture. Fibrosis is most prominent in the lungs, gastrointestinal tract, heart, tendon sheath, and perifascicular tissue surrounding skeletal muscle. Histopathologic examination of these organs shows homogeneous and relatively acellular connective tissue with thick, densely packed, and hyalinized collagen bundles.

## ORGAN-SPECIFIC PATHOLOGIC FINDINGS

### Skin

Skin fibrosis, the hallmark of SSc and other scleroderma-like syndromes, is accompanied by marked expansion of the dermis with obliteration of the hair follicles, sweat glands, and sebaceous glands and other skin appendages. Collagen fiber accumulation is most prominent in the reticular (deep) dermis and progressively involves the subjacent adipose layer with entrapment of fat cells (adipocytes). Early-stage SSc skin biopsies reveal dermal edema and sometimes striking perivascular cellular infiltrates composed of T lymphocytes and monocytes (Figure 83-3). Less commonly, mast cells and eosinophils may also be detected.[33,34] The proportion of α-smooth muscle actin–positive myofibroblasts, a mesenchymal cell type that is intermediate between fibroblasts and contractile smooth muscle cells and plays a major role in fibrogenesis, is increased in the lesional skin.[35]

With disease progression, the skin undergoes atrophy with loss of epidermal-dermal ridges and effacement of the rete pegs reminiscent of the changes seen in aging skin. The fibrotic dermis is largely acellular and contains dense accumulation of compact hyalinized collagen bundles, fibronectin, hyaluronic acid, and other structural proteins. Sweat glands and eccrine glands atrophy with loss of periglandular adipose tissue. The intradermal adipose layer interposed between the dermis and muscle is obliterated. In a double-blind study of SSc skin biopsies, the histologic grade of skin fibrosis was found to closely correlate with the extent of clinical skin involvement.[36] Reduction in the number of dermal lymphatic vessels can be marked and contributes to interstitial fluid accumulation and skin edema.[37] Paucity of dermal capillaries, also known as rarefaction, is associated with chronic tissue hypoxia, which increases expression of angiogenic factors such as vascular endothelial growth factor (VEGF). Evidence of tissue hypoxia is found in clinically uninvolved, apparently "normal" skin.[38]

Biochemical analysis shows that the collagens in the fibrotic dermis are normal, and relative proportions of the main fibrillar collagens (type I and type III) are comparable with those of normal skin.[39] In contrast, the minor nonfibrillar type VII collagen, which is normally restricted to the dermal-epidermal basement membrane zone, is abundant throughout the lesional dermis. Enzymes mediating post-translational collagen and elastin modification such as lysyl oxidases (LOXL2) and lysyl hydroxylase (PLOD2) are elevated, resulting in an increase in aldehyde-derived collagen cross-links, which may account for the dense sclerotic nature of the fibrotic dermis.[40]

Genome-wide expression profiling of lesional skin using microarray technology provides an increasingly clearer understanding of the activation events that underlie fibrosis. Results from several studies reveal altered gene expression patterns in SSc skin biopsy specimens compared with healthy control subjects. Remarkably, clinically involved and uninvolved skin samples appear to be indistinguishable in terms of their gene expression profiles. Many genes involved in cellular immunity and inflammation, ECM homeostasis, and the transforming growth factor-β

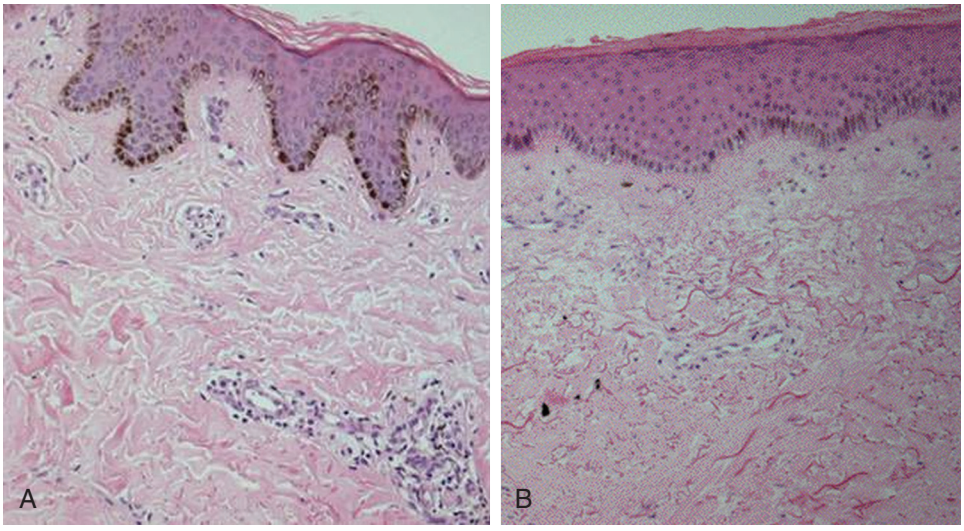

**Figure 83-3** Histology of skin in diffuse cutaneous systemic sclerosis. Perivascular infiltration is present in the dermis with inflammatory cells of multiple lineages. Microvascular endothelial cell activation and increased extra-cellular matrix deposition are also seen **(A).** Later, regression of the inflammatory features occurs. Secondary structures within the skin such as hair follicles and sebaceous and sweat glands are reduced, and rete pegs are flattened **(B).** Hematoxylin and eosin stain, original magnification ×40.

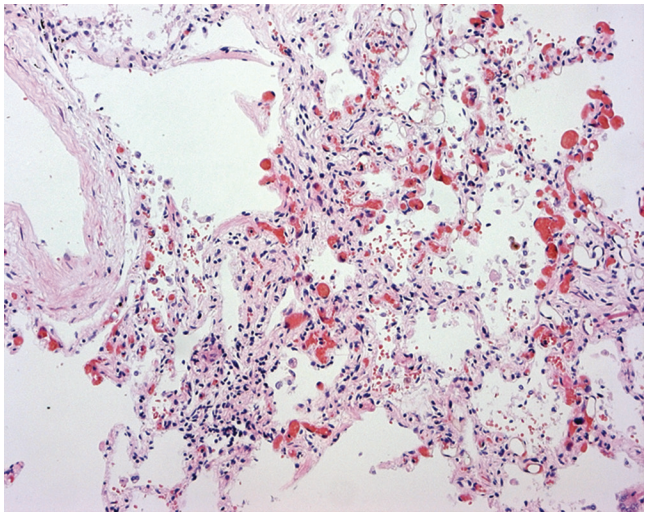

**Figure 83-4** Histologic appearance of the lung. Evidence of interstitial lung disease is common in systemic sclerosis. Although substantial variation exists in the appearance of lung histology, consistent features include reduction in air spaces and thickening of alveolar walls with matrix deposition. Inflammatory cell infiltrates may be prominent. A lung biopsy is rarely required for diagnosis.

(TGF-β), CCN2, IL-13, and Wnt signaling pathways show elevated expression in SSc skin.[41,42] Skin biopsy specimens from different patients with SSc show marked heterogeneity at the level of their "molecular signature," with distinct and reproducible patterns that define "intrinsic subsets."[43]

## Lungs

In early-stage SSc, the lungs show patchy infiltration of the alveolar walls with lymphocytes, plasma cells, macrophages, and eosinophils (Figure 83-4). At this stage, high-resolution computed tomography scanning of the lungs may show a ground-glass opacification pattern. With progression, interstitial lung fibrosis and vascular damage develop, often coexisting within the same lesions. Intimal thickening of the pulmonary arteries, best seen with elastin stain, underlies PAH and at autopsy is often found to be associated with multiple pulmonary emboli and myocardial fibrosis.

Lung fibrosis in SSc is characterized by expansion of the alveolar interstitium as a result of the accumulation of collagens and other connective tissue proteins. The typical histologic pattern of SSc-associated interstitial lung disease is nonspecific interstitial pneumonitis, which is characterized by mild to moderate interstitial inflammation, type II pneumocyte hyperplasia, and fairly uniform distribution of fibrosis.[44] Less commonly, SSc is associated with the usual interstitial pneumonia pattern that is characterized by scattered fibroblastic foci and patchy distribution of fibrosis and has a worse prognosis. Progressive alveolar septal thickening ultimately results in obliteration of the air spaces and honeycombing, as well as consequent loss of pulmonary blood vessels. This process impairs gas exchange and contributes to worsening of pulmonary hypertension. Extensive pulmonary fibrosis also may predispose to primary lung carcinoma.

## Gastrointestinal Tract

The gastrointestinal tract is virtually always affected in persons with SSc, and prominent pathologic changes are seen at any level from the mouth to the rectum. The esophagus is prominently involved, with fibrosis in the lamina propria, submucosa, and muscular layers and characteristic vascular lesions.[45] Replacement of the normal intestinal architecture results in disordered peristaltic activity, gastroesophageal reflux, gastroparesis and small bowel dysmotility, pseudo-obstruction, and bacterial overgrowth. Chronic gastroesophageal reflux is complicated by esophageal inflammation, ulcerations, stricture formation, and recurrent microaspiration. In up to one-third of patients with SSc who have severe gastroesophageal reflux, Barrett's esophagus develops, which is characterized by metaplasia of the normal squamous lining of the esophagus into columnar epithelium.[46] Because Barrett's metaplasia is a premalignant lesion associated with a greater than 30-fold increased risk of adenocarcinoma, patients with Barrett's esophagus need ongoing monitoring for dysplasia and adenocarcinoma.

## Kidneys

In the kidneys of a person with SSc, vascular lesions predominate, whereas glomerulonephritis is rare except in patients with overlap syndromes. Chronic renal ischemia is associated with shrunken glomeruli and other ischemic changes. Patients with acute scleroderma renal crisis have histopathologic changes indistinguishable from those in other forms of thrombotic microangiopathies associated with malignant hypertension.[47] Small interlobular and arcuate renal arteries show reduplication of elastic lamina, marked intimal proliferation (onion skinning), and fibrinoid necrosis of the arteriolar walls.[48] Of note, however, similar pathologic changes have also been reported in patients with SSc who do not experience a renal crisis. Intimal thickening leads to severe narrowing and total obliteration of the lumen and underlies microangiopathic hemolysis. Tubular changes such as flattening and degeneration of tubular cells occur as a result of vascular insufficiency. The clinical picture of scleroderma renal crisis may resemble thrombotic thrombocytopenic purpura. However, scleroderma renal crisis is not associated with reduced to absent levels or activity of von Willebrand factor–cleaving protease *(ADAMTS13)*. Figure 83-5 shows the characteristic histologic features associated with scleroderma renal crisis.

## Heart

At autopsy, evidence of cardiac involvement is found in up to 80% of patients with SSc.[49] Modest pericardial effusions are common, and occasionally, fibrosis and constrictive pericarditis may occur. Microvascular changes are prominent in the endocardium. A characteristic pathologic finding is myocardial contraction band necrosis, which is thought to reflect repeated episodes of ischemia-reperfusion as a result of "myocardial Raynaud's phenomenon."[50] Significant interstitial and perivascular fibrosis in the heart may occur in the absence of clinically evident heart involvement. Skeletal

muscle myositis in SSc is occasionally accompanied by acute myocarditis.[49]

### Pathologic Findings in Other Organs

Fibrosis of the thyroid glands is common, with broad bands of fibrous tissue in the thyroid gland and atrophy and obliteration of the follicles in the absence of inflammation. Abnormal thyroid function tests and anti-thyroid antibodies are common. Erectile dysfunction is frequent and may be a presenting manifestation of the disease in men. Pathologic examination shows extensive proliferative/obliterative changes in the penile blood vessels.[51] Fibrosis of the salivary and lacrimal glands in the absence of inflammation can occur and may be associated with Sjögren's syndrome. Synovial biopsies show fibrosis and characteristic vascular changes in the small arterioles.[52]

## ANIMAL MODELS OF SCLERODERMA

Animal models are indispensable research tools to facilitate the understanding of complex human diseases. Such models are used to identify the cellular and molecular components of the pathologic process, discover potential therapeutic targets, and develop and evaluate novel treatment strategies. Several animal models of SSc exist, although none fully reproduces the four cardinal features of the disease: obliterative and proliferative microangiopathy, autoimmunity, inflammation, and chronic multiorgan fibrosis.[53] However, as illustrated in Figure 83-6, particular animal models recapitulate selected features or stages of SSc. Broadly speaking, mouse models can be divided into four types: (1) naturally occurring, in which spontaneous mutations are associated with a genetically transmitted scleroderma-like phenotype such as tight skin (Tsk1/$^{+}$ mouse); (2) experimentally induced in which a scleroderma phenotype is elicited by chemical exposures or by manipulation of the immune system (bleomycin or angiotensin II–induced skin and lung fibrosis); (3) transplantation of HLA-mismatched bone marrow cells, resulting in a sclerodermatous graft-versus-host–like disease; and (4) genetic manipulations giving rise to engineered mouse strains with heritable scleroderma-like traits.

### Heritable Animal Models of Scleroderma

The Tsk1/$^{+}$ mutant is characterized by diffuse skin tightness and tethering to the underlying subcutaneous tissue. Whereas homozygous Tsk1 mice die in utero at 8 to 10 days of gestation, heterozygous (Tsk1/$^{+}$) mice survive and develop tight skin. In contrast to SSc, Tsk1/$^{+}$ mice show prominent subcutaneous hyperplasia but a relatively unremarkable dermis.[54] Furthermore, the lungs of Tsk1/$^{+}$ mice show emphysematous changes rather than fibrosis, and

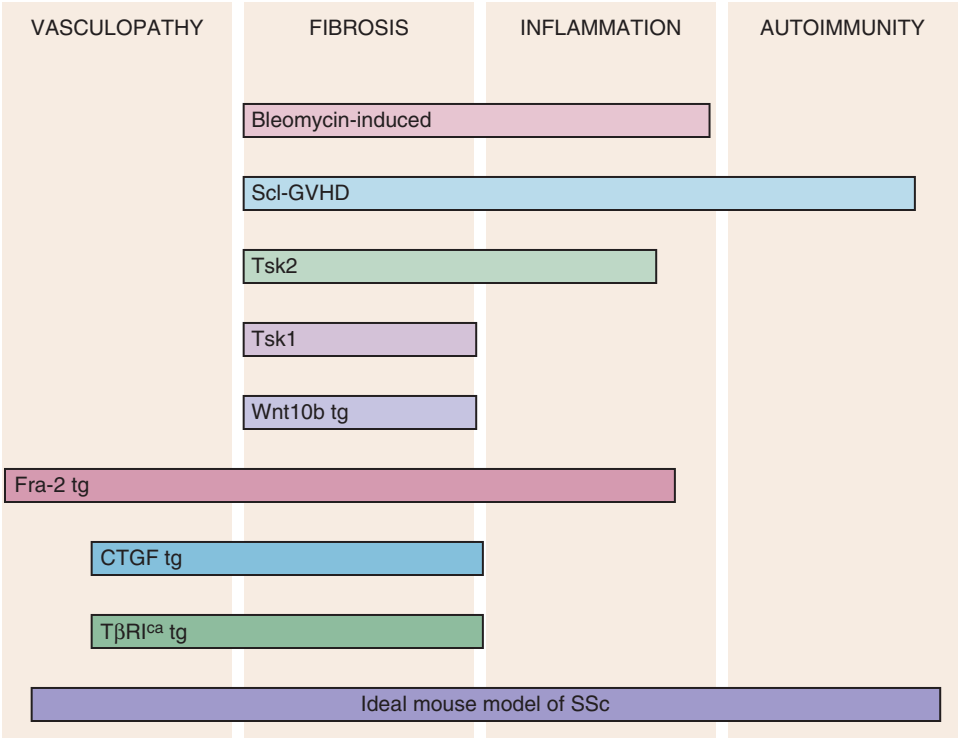

**Figure 83-6** Animal models of systemic sclerosis. Mouse models recapitulate selected pathophysiologic features of systemic sclerosis (SSc). Shown are the principal disease processes of SSc (inflammation, autoimmunity, microangiopathy, and fibrosis) and the extent to which they are represented in commonly used mouse models. CTGF, Connective tissue growth factor; GVHD, graft-versus-host disease; tg, transgenic. *(Modified from Distler JH, Distler O, Beyer C, Schett G: Animal models of systemic sclerosis: prospects and limitations.* Arthritis Rheum *62:2831–2844, 2010.)*

microangiopathy has not been reported. The Tsk1 mutation is an intragenic tandem duplication of the fibrillin-1 gene, giving rise to an abnormally large 450 kDa protein.[55] Fibrillin-1 is a widely distributed microfibril-associated ECM protein that modulates the latency and activation of TGF-β.[56] The accumulation of the abnormally large mutant fibrillin-1 might destabilize the matrix[57] or perturb the homeostatic control of TGF-β latency; however, the precise mechanisms linking the Tsk1/$^{+}$ fibrillin mutation to cutaneous hyperplasia are unknown. No corresponding fibrillin-1 mutations have been demonstrated in patients with SSc. Mutations throughout the fibrillin-1 gene cause Marfan's syndrome, characterized by bone overgrowth, ocular lens displacement, and aortic dilatation, associated with increased activity of TGF-β in multiple tissues. Patients with stiff skin syndrome, a rare Mendelian autosomal dominant condition with a childhood onset of skin fibrosis, have heterozygous mutations in the RGD domain of fibrillin-1. Genetically engineered mice harboring analogous fibrillin-1 mutations develop diffuse skin fibrosis associated with increased TGF-β signaling and activation of plasmacytoid DCs (pDCs) in the skin.[58]

The Tsk2 mouse strain spontaneously develops scleroderma-like skin changes by 4 weeks of age. In contrast to Tsk1/$^{+}$ mice, Tsk2/$^{+}$ mice have a thickened dermis infiltrated with mononuclear inflammatory cells and show evidence of autoimmunity. The Tsk2 phenotype, originally induced in normal mice by ethyl nitrosourea, is due to a missense mutation in the amino-terminal end of the *COL3A1* gene—mutations that previously have been associated with Ehlers-Danlos syndrome.[59]

## Inducible Animal Models of Scleroderma

Chronic skin and lung fibrosis (Figure 83-7) can be induced in BALB/c or C57 mice by subcutaneous injections of bleomycin, angiotensin II, oxidative agents such as hydroxyl radicals or hypochlorite, and ligands of TLRs. The sequence of histopathologic changes elicited by these agents recapitulates those seen in SSc: early mononuclear cell infiltration and macrophage activation, expression of cytokines such as TGF-β, IL-4, IL-6, IL-13, and chemokines such as monocyte chemotactic protein-1 (MCP-1), followed by progressive dermal fibrosis with excessive collagen deposition and accumulation of α-smooth muscle actin–positive myofibroblasts and disappearance of the intradermal white adipose tissue.[60,61] Although microangiopathic changes or autoantibodies are not prominent and skin fibrosis remains limited in extent and duration in chemically induced mouse models of scleroderma, in light of their reproducibility, relative strain independence, and ease of induction, these mouse models remain indispensable for investigating specific cell types and transdifferentiations, molecules, and pathways in the development and treatment of fibrosis. Subcutaneous injection of constitutively active TGF-β receptor I is sufficient to induce local dermal fibrosis. Transplantation of bone marrow or spleen cells into minor histocompatibility locus–mismatched recipient mice results in chronic sclerodermatous graft-versus-host–like disease with interstitial and perivascular fibrosis in the skin and lung, as well as autoimmunity.[62] Skin fibrosis is preceded by mononuclear cell and macrophage activation with elevated TGF-β and chemokine expression.

### Genetic Manipulations in Mice Giving Rise to Scleroderma-like Phenotypes

Mouse strains with genetic gain-of-function or loss-of-function modifications resulting in spontaneous scleroderma-like phenotypes have been created. These transgenic, knockin, and knockout mice provide robust novel experimental tools in scleroderma research. Mouse strains with constitutive or inducible expression of TGF-β signaling in fibroblasts recapitulate key clinical, histologic, and biochemical features of SSc and provide support for the role of perturbed TGF-β signaling in pathogenesis.[63,64] Other promising transgenic models of SSc include mice that overexpress CTGF, PDGF receptor (PDGFR)-α, Wnt10b, and Fra-2 and mice null for caveolin-1, uPAR, and Fli-1.[65] Scleroderma-like fibrotic, vascular, and calcific changes in the skin, and in some cases in the lungs, develop spontaneously in these mice. Other genetically engineered mice show increased sensitivity to the induction of fibrosis. Examples include *T-bet* null and *VEGF* null mice. These emerging mouse models provide new, exciting research opportunities for the discovery of molecules and pathways that underlie the pathogenetic features of SSc.

## PATHOGENESIS

### Integrated Overview

The pathogenesis of SSc is complex, and as previously discussed, existing animal models only imperfectly capture its diverse pathologic and clinical attributes and natural history. A comprehensive paradigm for SSc pathogenesis must encompass and integrate the following cardinal pathomechanisms: vascular damage, inflammation with activated innate and adaptive immunity, and fibroblast activation resulting in generalized tissue fibrosis. Evidence exists for each pathomechanism in patients with SSc; however, the contribution of individual processes to the disease manifestations varies from one patient to another. As illustrated in Figure 83-1, complex and dynamic interplay between these distinct processes is responsible for initiating, amplifying, and sustaining tissue damage underlying the symptoms and signs of SSc.[66]

## Vasculopathy

Vascular injury is an initiating proximal event in SSc (see Figure 83-5). Evidence of vascular involvement is early and widespread, and its progression over time is associated with significant clinical sequelae.[67] The presence of nail-fold microvascular changes in a person with Raynaud's phenomenon identifies an elevated risk of progression to SSc, indicating that microvasculopathy precedes other clinical manifestations of the disease.

## Vascular Injury and the Activated Endothelium

The initial vascular insult in SSc might be triggered by circulating factors such as (unidentified) cytotoxic molecules or T cell–derived proteolytic granzymes.[68] Other potential causes include anti-endothelial cell and endothelial cell receptor antibodies, vasculotropic viruses, inflammatory cytokines, reactive oxygen species (ROS), and other forms of environmental stress. Vascular injury in SSc causes activation of endothelial cels, with increased expression of

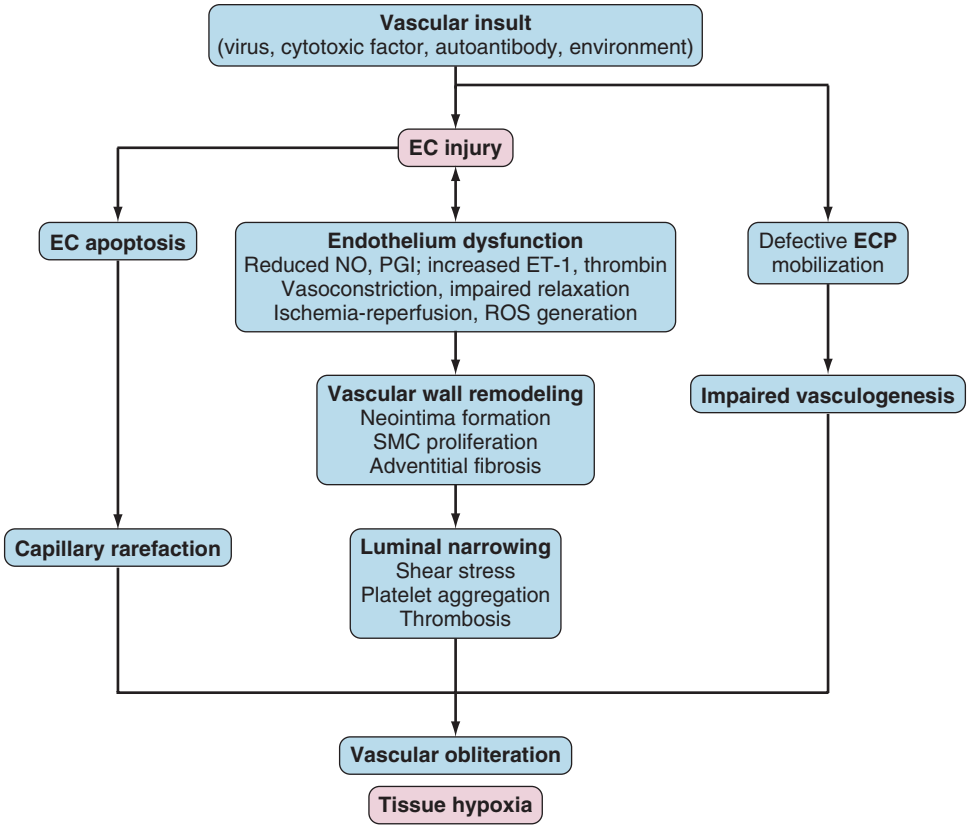

**Figure 83-8** Pathogenesis of vasculopathy. An initial vascular insult results in endothelial cell (EC) injury and activation, with reversible functional changes, increased expression of adhesion molecules, and enhanced leukocyte diapedesis resulting in perivascular inflammation. Damaged endothelium promotes platelet aggregation and thrombin release and shows impaired production of vasodilators such as nitric oxide (NO), increased production of vasoconstrictors such as endothelin-1 (ET-1), and release of reactive oxygen species (ROS). Consequent vasoconstriction and defective vasodilation aggravate vascular damage, leading to irreversible and progressive vascular wall remodeling, luminal occlusion, platelet aggregation, in situ thrombosis, and tissue hypoxia. Loss of blood vessels may be further compounded by insufficient vasculogenesis. ECP, Endothelial cell progenitor; PGI, prostaglandin I; SMC, smooth muscle cell.

vascular endothelial cell adhesion molecule-1 and E-selectin and altered secretion of vasoactive mediators, followed by platelet activation and activation of the thrombotic and fibrinolytic cascades.[67] Evidence also shows that activated endothelial cells in the injured arterioles and capillaries transdifferentiate into mesenchymal cells via *endothelial-mesenchymal transition* driven by TGF-β and Notch and are associated with loss of endothelial markers such as CD31 and acquisition of mesenchymal markers such as α–smooth muscle actin. Platelet activation is prominent in SSc and is associated with release of thromboxane $A_2$, PDGF, and TGF-β and activation of thrombin, which promote coagulation, potentiate vasoconstriction, and directly stimulate fibroblast activation and myofibroblast transdifferentiation. Structural cells in the walls of small blood vessels called pericytes show marked hyperplasia in lesional skin and express the surface marker Thy-1 (CD90) and receptors for PDGF.[69,70]

Prominent functional abnormalities of the vascular endothelium include impaired production of and responsiveness to endothelium-derived vasodilators such as nitric oxide, thrombomodulin, calcitonin gene-related peptide, and prostacyclins. Additionally, dysregulation of sensory and sympathetic nerves results in decreased release of vasodilator neuropeptides and increased expression of vasoconstrictors such as α2-adrenoreceptors on vascular smooth muscle cells. The ensuing imbalance of vasodilators and vasoconstrictors impairs blood flow responses. Recurrent episodes of ischemia-reperfusion promote oxidative stress with the generation of $H_2O_2$ and other oxygen free radicals. Damaged microvessels show increased vascular permeability, and injured endothelial cells promote and transendothelial leukocyte migration. Platelets are exposed to subendothelial structures, which further aggravates platelet aggregation. Activated endothelial cells release the extremely potent vasoconstrictor ET-1, which promotes leukocyte adhesion, vascular smooth muscle cell proliferation, and fibroblast activation (Figure 83-8). Levels of ET-1 are elevated in lesional tissue, in the blood, and in bronchoalveolar lavage fluids in persons with SSc.[71]

## Vascular Damage and Failure of Compensatory Vascular Repair

In medium-sized and larger vessels, a combination of intimal and medial hypertrophy and adventitial fibrosis causes progressive luminal narrowing. Together with endothelial cell apoptosis and thrombosis, the process culminates in obliterative vasculopathy with the characteristic paucity of blood vessels seen by angiography in late-stage SSc. Loss of

microvasculature results in reduced blood flow and chronic tissue hypoxia, which induces hypoxia-inducible factor-1 (HIF-1)–α dependent genes such as VEGF and its receptors.

The balance between angiogenic and antiangiogenic factors is fundamentally dysregulated in SSc. Plasma levels of the angiogenesis inhibitor endostatin, a degradation product of type XVIII collagen, are elevated.[72] Other investigators found elevated levels of the angiogenic factors such as VEGF, basic fibroblast growth factor, IL-8, CXCL-12, and PDGF. Furthermore, levels of VEGF and its receptors was also found to be elevated in lesional tissue.[73,74] It is unclear why, in the face of tissue hypoxia and elevated angiogenic factors, there is a failure of compensatory growth of new blood vessels via angiogenesis or vasculogenesis in SSc, resulting in progressive loss of blood vessels. An intriguing possibility is that VEGF premessenger RNA (pre-mRNA) undergoes alternate splicing to generate an antiangiogenic isoform VEGF, called $VEGF_{165b}$. $VEGF_{165b}$ is overexpressed in the skin in patients with SSc, suggesting that an alternate splicing event causing a switch from angiogenic to antiangiogenic VEGF isoform plays a crucial role in the failure to mount an appropriate compensatory angiogenic response to hypoxia in SSc.

Vasculogenesis, or de novo blood vessel formation, is a process critically dependent on bone marrow–derived circulating endothelial progenitor cells (EPCs) and their differentiation into mature endothelial cells. Recent studies implicate defective vasculogenesis as an explanation for loss of blood vessels in SSc. A reduction in the number of $CD34^+$ EPCs and their impaired differentiation into mature endothelial cells has been documented in patients with SSc.[75-77] Because EPCs are required for physiologic vasculogenesis in ischemic tissues, defective progenitor cell mobilization or function compromises the vascular repair. Whether the reduction in circulating EPCs in SSc is due to diminished release from the bone marrow as a result of fibrosis or "exhaustion," destruction in the peripheral circulation, or some other process remains unresolved.

## Hypoxia

The widespread microangiopathy and resultant capillary loss in SSc leads to diminished blood flow and consequent hypoxia of affected tissues. With the onset of fibrosis, excessive ECM accumulation increases diffusion distance from blood vessels to cells, further aggravating tissue hypoxia.[78] Hypoxia is itself a potent inducer of the basic helix-loop-helix transcription factors HIF-1α and HIF-1β, which, under normoxic conditions, are undetectable as a result of rapid and efficient proteosomal degradation mediated by the von Hippel–Lindau tumor suppressor. In hypoxic cells, the von Hippel–Lindau protein is unable to bind to its target, and therefore HIF-1α is protected from degradation and translocates into the nucleus, where it binds to hypoxia-responsive DNA elements and induces the transcription of hypoxia-regulated genes involved in erythropoiesis, angiogenesis, and glucose metabolism. Hypoxia is also a potent in vitro and in vivo stimulus for genes involved in ECM, including collagens, prolyl hydroxylases, and lysyl oxidase, and directly stimulates epithelial cell–myofibroblast differentiation.[79,80] These and other hypoxia-induced profibrogenic responses are partially mediated by autocrine TGF-β. Compelling experimental support for the role of hypoxia in fibrosis is provided by a recent study, which shows increased fibrosis and Wnt-β-catenin signaling in mice with myeloid cell-specific deletion of VEGF, culminating in exacerbation of fibrosis.[81]

A state of tissue hypoxia in SSc has been documented by noninvasive means, and cutaneous oxygen concentrations inversely correlate with skin thickness. With the use of a needle electrode inserted into the dermis, patients with SSc were found to have significantly reduced levels of $pO_2$ compared with control subjects (23.7 mm Hg vs. 33.6 mm Hg). Interestingly, HIF-1α was not detectable in the lesional skin.

## Oxidative Stress and Reactive Oxygen Species

Oxidative stress results from an imbalance between the generation of chemically reactive oxygen-derived molecules called ROS and antioxidant defense mechanisms. Substantial evidence indicates enhanced oxidative stress and elevated ROS generation in patients with SSc and supports their role in the pathogenesis of SSc.[82,83] In SSc, ROS are generated from the endothelium in response to episodes of ischemia-perfusion and from fibroblasts exposed to mediators such as TGF-β, PDGF, angiotensin II, and ET-1, or in response to stimulatory anti-PDGFR antibodies. Moreover, explanted SSc dermal fibroblasts and monocytes spontaneously produce ROS.[84] Although several cellular enzymes, as well as mitochondria, can generate ROS, in SSc the membrane-associated nicotinamide adenine dinucleotide phosphate oxidase Nox4 appears to play a prominent role. Hydrogen peroxide and other oxygen free radicals can stimulate collagen synthesis, myofibroblast differentiation, and secretion and activation of TGF-β and Wnt-β-catenin pathways, as well as induce cellular senescence.

# INFLAMMATION AND IMMUNE DYSREGULATION IN THE PATHOGENESIS OF SYSTEMIC SCLEROSIS

Recent discoveries from genetic and genomic studies, along with the application of high throughput cellular phenotyping technologies, have prompted a resurgence of interest in the role of immune dysregulation in SSc. Persons with SSc might be genetically predisposed to develop dysregulated innate and adaptive immune responses. Lesional skin and lungs show early and prominent perivascular accumulation of mononuclear cells, macrophages, and pDCs, whereas circulating T cells, B cells, monocytes, and DCs show evidence of activation and polarization. The characteristic "type I IFN signature" prominent in SLE and other autoimmune diseases is also seen in SSc. Autoimmunity manifested by the presence of highly specific and mutually exclusive autoantibodies is prominent throughout the course of the disease (Figure 83-9). The strong genetic associations between SSc and the class II HLA locus, as well as numerous genes related to B and T cell function and innate immunity, provide strong support for an immunologic basis of SSc. Ongoing therapeutic trials are evaluating the efficacy of global (myeloablative) and selective immunomodulatory interventions in SSc and suggest that the immune system contributes to progressive disease.

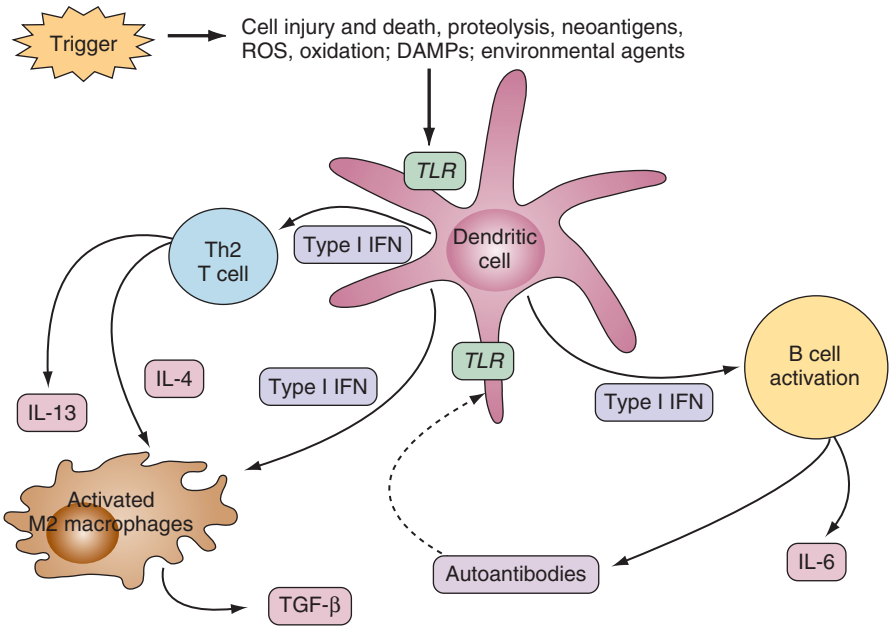

**Figure 83-9** Complex immune dysregulation in scleroderma. An inciting event such as infection, oxidative damage, necrotic/apoptotic cell debris, or environmental toxins causes activation of dendritic cells, possibly via Toll-like receptors (TLRs). Activated dendritic cells produce type I interferon (IFN), which causes T helper (Th)2 T cell polarization, monocyte differentiation to an alternately activated (M2) phenotype, and B cell activation with plasma cell maturation and production of autoantibodies. Autoantibodies form immune complexes that in turn further induce type I IFN production via TLR signaling. Th2-polarized T cells and M2 macrophages secrete profibrotic chemokines and cytokines, inducing fibroblast activation. Additional T cell subsets such as regulatory T cells and Th17 also may be involved. DAMPs, Damage-associated molecular patterns; ROS, reactive oxygen species; TGF-β, transforming growth factor-β.

## Cellular Effectors of Dysregulated Immunity: T Cells, B Cells, and Monocytes/Macrophages

### T Cell Subsets and Activation

T cell activation is evident in SSc lesional tissues, as well as in peripheral blood, and appears to play a direct role in tissue injury. In the early stage of the disease, activated CD4 and CD8 T lymphocytes, monocytes/macrophages, and B cells, along with eosinophils, mast cells, and natural killer cells, are observed in a perivascular distribution in the lesional skin, lungs, and other affected organs and can be detected in these tissues before the appearance of fibrosis.[85] In situ hybridization studies show that fibroblasts with prominent procollagen gene expression in early-stage SSc skin are adjacent to inflammatory cells, suggesting that they or their soluble products play a direct role in fibroblast activation.[86] The extent of lymphocytic tissue infiltration correlates with the severity and progression of skin fibrosis.

Tissue-infiltrating T cells are predominantly $CD3^+$ and $CD4^+$, express markers of activation (CD69, CD45, HLA-DR, and IL-2R), and display restricted T cell receptor signatures, suggesting oligoclonal T cell expansion in response to an as-yet unidentified antigen.[87] In the lungs, a predominance of $CD8^+$ and γ/δ T cells is observed.[88] Currently it is not known if T cells in lesional tissue are activated nonspecifically (by cytokines or chemokines) or specifically in response to antigen. Evidence of T cell activation in SSc is also detected in the peripheral blood, with elevated serum levels of IL-2 and IL-2R and chemokines receptors, spontaneous cytokine secretion, and increased expression of leukocyte function-associated antigen 1 (LFA-1) and α1 integrins, which enable T cells to adhere directly to endothelium and fibroblasts. At the same time, vascular endothelial cells express intercellular adhesion molecule-1 (ICAM-1), E-selectin, and other adhesion molecules that facilitate leukocyte diapedesis. Peripheral blood lymphocytes show the "IFN signature" defined by the induction of type I IFN-inducible genes.[89-91]

### T Helper 1/T Helper 2 Cytokine Balance and Polarized Immune Responses

A skewed balance between T helper (Th)1 and Th2 cytokines is a characteristic of fibrosis. Th2 cells secrete abundant IL-4, IL-5, and IL-13, but only low levels of the hallmark Th1 cytokine IFN-γ. Th2 cytokines directly stimulate collagen synthesis, myofibroblast transdifferentiation, and production of TGF-β, a potent stimulus for ECM accumulation, whereas IFN-γ blocks these responses and exerts antifibrotic effects. The Th2 skewing of the immune response thus creates a profibrotic environment.

Support for the significance of a Th2-polarized immune response in fibrosis comes from animal studies, which show that in vitro Th2-polarized T cells induce fibrosis when they are passively transferred in mice. Moreover, in mice lacking the T-bet transcription factor, which directs Th1 differentiation, exaggerated skin fibrosis develops in response to bleomycin.[92,93]

Patients with SSc display an altered Th1/Th2 cytokine balance with a predominant Th2 profile. For example, IFN-γ serum levels and in vitro IFN-γ production by peripheral blood monocytes are reduced in persons with SSc. Microarray analysis of SSc peripheral blood leukocytes

showed elevated expression of GATA3, which controls Th2 polarization. Cloned $CD4^+$ T cells from SSc skin biopsies secrete IL-4 but not IFN-γ.[94] T cell lines generated from SSc skin biopsies or alveolar fluid produce high levels of Th2 cytokines, and the Th2 predominance predicts accelerated decline in lung function.[95,96] Proteomic and DNA microarray analysis also demonstrated a Th2 cytokine predominance in SSc bronchoalveolar lavage fluids and $CD8^+$ lymphocytes. Furthermore, a longitudinal study of patients with SSc showed that skin improvement over time was associated with a decline in serum levels of Th2 cytokines and a concomitant increase in IL-12, a Th1 cytokine.[97]

### Other T Cell Subsets in SSc

Th17 lymphocytes are implicated in the pathogenesis of rheumatoid arthritis and other inflammatory diseases. Patients with SSc have increased numbers of IL-17–producing $CD4^+$ T cells in both the peripheral blood and bronchoalveolar lavage fluid.[98] The presence of a Th1, Th2, or Th17 predominant immune response might be useful in identifying clinical phenotypes in SSc.

Suppressor Tregs are important in controlling autoimmunity. One study found that although the frequency of peripheral blood Tregs was increased in patients with SSc, they showed impaired suppressive activity and defective secretion of TGF-β and IL-10.[99] Other studies demonstrated reduced numbers of $Foxp3^+$ $CD4^+$ T cells in the lesional skin compared with other inflammatory skin diseases.

## Monocytes and Macrophages

Bone marrow–derived phagocytic monocytes, and the macrophages they give rise to, regulate both innate immunity and tissue repair by virtue of their ability to secrete paracrine regulators of cell function, and they play a fundamental role in vascular injury and fibrosis in SSc β.[100]

Monocytes are a major source of cytokines and chemokines, including IL-1, TNF, MCP-1, PDGF, and TGF-β, all of which are important in inflammatory and fibroproliferative processes. Additionally, monocytes produce collagenases and other matrix-degrading enzymes, as well as their inhibitors. In early-stage SSc, macrophages are prominent in the lesional skin and express Siglec-1 and AIF-1, which are markers of IFN-induced activation. Macrophages undergo polarization in response to specific stimuli, with the alternatively activated (M2) macrophage phenotype typically induced in response to IL-4 and TGF-β.

In patients with SSc, circulating monocytes express elevated levels of CCL18 and CD163, an M2 monocyte/macrophage marker. Serum levels of soluble CD163 are also elevated and correlate with disease severity. The number of macrophages expressing CD163 and CD204 is also elevated in the lesional skin. Another study showed that multiple macrophage activation markers are elevated in SSc lungs and correlate with the severity and progression of interstitial lung disease. In animal models of fibrosis, macrophages expressing the scavenger macrophage receptor with collagenous structure (MARCO) accumulate in affected organs. In some cases, evidence of local mast cell and eosinophil activation and degranulation are prominent in lesional skin.

## Dendritic Cells

DCs bearing CD11c surface markers are potent antigen-presenting cells that reside in the skin and other tissues. DCs bridge innate and adaptive immunity, and by modulating T cell, B cell, and monocyte/macrophage function, they shape the immune response (see Figure 83-9). pDCs are primarily known as the major source of type I IFN and play a fundamental role in innate anti-viral immunity. pDCs can also secrete fibrogenic cytokines, including TGF-β, suggesting that they participate in fibrogenesis independent of their T cell–stimulatory properties. TLR7 and TLR9 on pDCs contribute to the pathogenesis of SLE by recognizing endogenous DNA and RNA in the form of immune complexes, leading to production of type I IFN. Recent studies show that $CD11c^+$ DCs accumulate in lesional tissue in animal models of fibrosis and in patients with SSc. As an example, $BDCA2^+$ pDCs were found to be abundant in the skin from patients with early diffuse cutaneous (dc)SSc and were shown to secrete CXCL4, also known as platelet factor 4.[101] Prominent accumulation of $CD317^+$ pDCs secreting type I IFN and IL-6 in lesional dermis from transgenic mice harboring the stiff skin syndrome fibrillin-1 mutation was reported. In this model, selective pDC depletion abolished skin fibrosis.[58] In SSc, activated pDCs might directly or indirectly modulate activation of resident fibroblasts. Moreover, peripheral blood monocyte–derived DCs in SSc show enhanced ex vivo activation upon incubation with SSc sera containing topoisomerase-1 antibodies and enhanced responses to TLR2/3 ligands with increased secretion of IL-6 and IL-10.

# HUMORAL AUTOIMMUNITY AND B CELLS

## Autoantibodies in Scleroderma: Pathogenetic Considerations

Humoral autoimmunity, manifested by serum autoantibodies with multiple antigenic specificities, can be detected in virtually all patients. The presence of SSc autoantibodies assists with diagnosis and classification, as well as in predicting organ-specific complications and clinical course. In contrast, a direct pathogenic role of SSc autoantibodies in tissue damage has not been conclusively established. Autoantibodies in SSc tend to be highly specific and mutually exclusive and are strongly associated with particular disease phenotypes and immunogenetic backgrounds. Some studies suggest that the levels of autoantibodies, particularly anti-DNA topoisomerase I, might correlate with the extent of skin and lung fibrosis and fluctuate with disease activity.

Various hypotheses exist to explain the generation of autoantibodies in SSc. Self-antigens such as DNA topoisomerase I might, in the presence of ROS, undergo proteolytic cleavage, exposing cryptic epitopes that break immune tolerance.[102] Other potential mechanisms include molecular mimicry as a consequence of viral infection, chronic B cell hyper-reactivity, and altered expression or subcellular localization of potential autoantigenic peptides. Alternately, SSc autoantibodies might be produced by B cells activated by endogenous TLR ligands such as nucleic acid–containing cellular debris.

Recent studies in SSc report the presence of functional antibodies that are directed against ECM components, cell surface receptors, fibroblasts, and endothelial cells. Stimulatory autoantibodies can induce target cell activation or apoptosis in vitro.[103,104] In one study, autoantibodies against PDGF receptors were detected in patients with SSc and induced ROS generation and myofibroblast differentiation in cultured fibroblasts. It is not known if these autoantibodies precede, or are consequent to, fibrosis, and their direct pathogenic role in SSc remains to be established.

### B Cells in Scleroderma

Recent reports and clues from genetic studies provide evidence for a potential direct role for B cells in the pathogenesis of SSc. B cells have multiple immune regulatory functions in addition to the generation of antibodies. These functions include antigen presentation, cytokine production, lymphoid organogenesis, and T cell differentiation. Candidate gene and GWA studies in SSc have implicated several B cell genes, including *BANK1, BLK, CSK*, and *PTPN22*, all of which are involved in regulating B cell signaling. Although B cells were found in SSc-associated interstitial lung disease biopsy specimens,[105] they are not generally prominent in lesional skin. Nevertheless, microarrays demonstrate molecular signatures indicative of B cell activation in SSc skin biopsy specimens. Patients with SSc display intrinsic B cell abnormalities, with elevated numbers of naïve B cells, reduced numbers of plasma cells, and increased expression of activation markers CD95 and CD86, as well as CD19, a signaling cell surface receptor that regulates intrinsic and antigen receptor–induced B cell responses.[106] Transgenic mice that overexpress CD19 develop spontaneous autoimmunity and high titers of antitopoisomerase I antibodies. Chronic B cell activation in SSc may not only account for autoantibody production but also may contribute directly to fibrosis, because activated B cells secrete TGF-β and IL-6, which directly stimulate fibroblasts. Levels of BAFF (B cell survival factor B cell activating factor belonging to the TNF family) are elevated in the serum and in lesional skin, as is the expression of the BAFF receptor on B cells. B cell depletion in the mouse attenuates scleroderma, and small clinical trials of B cell depletion in SSc have reported clinical improvement.

### Type I Interferon Signature and Innate Immune Signaling: Similarities to Systemic Lupus Erythematosus

Stimulation of pDCs by ligands of TLR3, TLR7, and TLR9 results in robust secretion of type I IFN. Accordingly, the presence of IFN or IFN-dependent cellular responses suggests ongoing TLR-mediated innate immune signaling. Type I IFNs (α and β) are themselves potent modulators of innate immunity. Elevated expression of IFN-regulated genes (the "IFN signature") in peripheral blood cells, indicative of their exposure to IFN in the circulation or in the periphery, was first described in patients with SLE.[107] Circulating immune complexes containing antibodies to nucleic acids serve as endogenous TLR ligands that stimulate type I IFN secretion by pDCs and macrophages. Similar to SLE, a prominent IFN signature is detected in leukocytes from patients with SSc. Indeed, a recent study reported that the most highly expressed genes in SSc peripheral blood leukocytes were IFN-regulated.[90] Moreover, in normal leukocytes, incubation with SSc sera induced secretion of IFN, indicative of TLR activation by nucleic acid–containing immune complexes in the serum.[108] By identifying a role for TLRs and type I IFNs in SSc, these observations, along with immunogenetic studies, reveal important similarities between SLE and SSc. The reasons why these two related autoimmune diseases display largely nonoverlapping clinical phenotypes remain elusive. The direct pathogenetic role of type I IFN in SSc microangiopathy and fibrosis and the mechanisms responsible remain to be established.

## FIBROSIS

Fibrosis, characterized by replacement of normal tissue architecture with stiff paucicellular connective tissue, is the pathologic hallmark of SSc and represents a form of aberrant wound healing. Fibrosis is the end result of a complex series of vascular and immune-mediated responses to injury in a genetically predisposed individual. As illustrated in Figure 83-10, injured or activated vascular and immune cells produce soluble mediators, autoantibodies, and ROS that in turn induce and propagate mesenchymal cell activation and differentiation in a variety of tissue, culminating in excessive and ultimately irreversible ECM accumulation.[109]

### Extra-cellular Matrix

Connective tissue consists of a cellular compartment of resident fibroblasts and myofibroblasts and infiltrating cells embedded in an ECM composed of large structural proteins such as collagens, proteoglycans, elastin, microfibrils, and adhesive proteins. The ECM also serves as a reservoir sequestering growth factors and matricellular proteins that control the differentiation, function, and survival of mesenchymal cells. Excessive ECM accumulation in fibrosis results from overproduction by fibroblasts in response to autocrine and paracrine signals such as cytokines and chemokines; hypoxia and ROS; signals from the surrounding ECM; or via cell-cell interactions (Table 83-3). Impaired ECM degradation and turnover, as well as expansion of the tissue reservoir of ECM-producing mesenchymal cells, also play roles.

### Regulation of Collagen Synthesis

The collagens belong to a family of more than two dozen structural proteins with critical roles in organ development, growth, and differentiation. The skin, bones, and tendons are composed largely of type I collagen, the most abundant protein in mammals, with smaller amounts of associated type III collagen. Type II collagen is found mainly in articular cartilage, whereas type IV collagen is found in the basement membranes. The fibrillar collagens consist of three α chains wound into a characteristic triple helix. This structure is made possible by the presence of a glycine at every third residue of repeating Gly-X-Y sequence, where X is frequently a proline and Y is frequently a hydroxyproline. During their biosynthesis, fibrillar collagens undergo

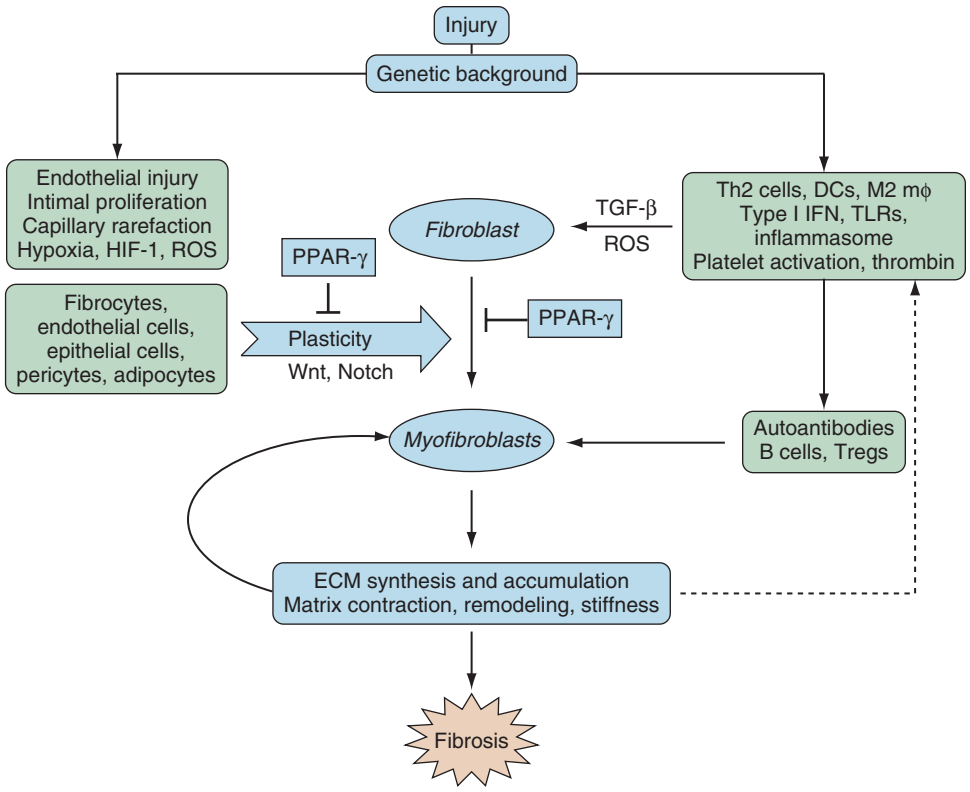

**Figure 83-10** Pathogenesis of fibrosis. Fibrosis is the end result of immune dysregulation and vascular damage and hypoxia. Injury causes vascular damage, perivascular inflammation, and innate immune signaling, with oxidative stress, secretion of inflammatory and fibrogenic cytokines and chemokines, autoantibodies, fibroblast activation, and myofibroblast accumulation. Circulating mesenchymal progenitor cells traffic to and accumulate within the lesional tissue and transdifferentiate into fibrotic fibroblasts, accelerating matrix accumulation. Tissue hypoxia, matrix remodeling, and stiffness further contribute to fibroblast activation, which causes disruption of tissue architecture and organ failure. DCs, Dendritic cells; ECM, extracellular matrix; HIF-1, hypoxia-inducible factor-1; IFN, interferon; PPAR-γ, peroxisome proliferator-activated receptor-γ; ROS, reactive oxygen species; TGF-β, transforming growth factor-β; Th2, T helper 2; TLRs, Toll-like receptors.

extensive enzymatic modifications inside the cell followed by additional extra-cellular maturation and assembly. Covalent cross-linking stabilizes the collagen fiber network in the extra-cellular space.

Environmental cues allow fibroblasts to respond to dynamic tissue requirements during development and wound healing. Type I collagen synthesis is regulated by cytokines, growth factors, ROS, hypoxia, and cues provided by the ECM (Table 83-3). The genes encoding the various collagens harbor cis-acting regulatory elements recognized by DNA-binding transcription factors such as Sp1, Ets1, Smad2/3, Egr-1, and CCAAT-binding factor (CBF) that stimulate collagen gene transcription, as well as Sp3, C/EBP, YB1, c-Krox, and Fli-1 that suppress collagen gene transcription.[109] These transcription factors interact with one another and with non–DNA-binding cofactors, scaffold proteins, chromatin-modifying enzymes such as p300/CBP, PCAF, and histone deacetylases; their DNA-binding activities and protein-protein interactions and post-translational modifications are also controlled by extra-cellular cues. Enzymes that modify chromatin structure, causing it to unwind, enhance DNA-binding factor access to cognate cis-acting regulatory sequences and facilitate transcription. Alterations in the levels, activities, or interactions among the various transcription factors, cofactors, and chromatin-modifying enzymes contribute to persistent fibroblast activation in fibrosis.

## Effector Cells of Fibrosis: Fibroblasts

Fibroblasts are versatile spindle-shaped cells distributed in different parenchymal tissues that are capable of both ECM synthesis and resorption. Although unstimulated fibroblasts are biosynthetically quiescent, under the influence of appropriate extra-cellular cues they secrete ECM macromolecules and proteolytic enzymes, growth factors, cytokines and chemokines; adhere to and contract connective tissue; and transdifferentiate into myofibroblasts. Together, these biosynthetic, pro-inflammatory, contractile, and adhesive functions enable fibroblasts to execute effective wound healing. In contrast to physiologic ECM maintenance where the fibroblast repair program is self-limited, pathologic fibrosis is characterized by uncontrolled fibroblast activation that results in exaggerated and persistent ECM accumulation and remodeling. Recent DNA microarray studies reveal that fibroblasts derived from diverse anatomic locations retain markedly different patterns of gene expression.[110] This apparent "positional memory" of fibroblasts is governed by genetic imprinting by the homeobox (HOX) family transcription factors.

**TABLE 83-3** Extra-cellular Factors Implicated Fibrosis in Systemic Sclerosis

| Signal | Primary Cellular Source |
|---|---|
| TGF-β | Inflammatory cells (macrophages, T cells), platelets, fibroblasts |
| PDGF | Platelets, macrophages, fibroblasts, endothelial cells |
| CTGF/CCN2 | Fibroblasts |
| IGF-1 | Fibroblasts |
| IL-1α | Keratinocytes, macrophages |
| IL-4, IL-13 | Th2 lymphocytes, mast cells |
| IL-6 | Macrophages, B cells, T cells, fibroblasts |
| Chemokines (MCP-1, MCP-3) | Neutrophils, epithelial cells, endothelial cells, fibroblasts |
| Fibroblast growth factor | Fibroblasts |
| ET-1 | Endothelial cells |
| Wnt ligands | Developmental pathway aberrantly reactivated |
| Notch/Jagged | Developmental pathway aberrantly reactivated |
| Hypoxia | Hypoxic underperfused tissue |
| ROS | Generated from activated macrophages, fibroblasts, endothelial cells |

CTGF, Connective tissue growth factor; ET-1, endothelin-1; IGF-1, insulin-like growth factor-1; MCP, monocyte chemotactic protein; PDGF, platelet-derived growth factor; ROS, reactive oxygen species; SSc, systemic sclerosis; TGF-β, transforming growth factor-β.

## Effector Cells of Fibrosis: Myofibroblasts, Pericytes, Endothelial Cells, and Cellular Plasticity

In fibrosis, the tissue reservoir of activated matrix-modifying mesenchymal cells is expanded not only by proliferation of resident fibroblasts but also by transdifferentiation of other cell types, as well as by the influx of bone marrow–derived progenitor cells. Myofibroblasts, characterized by the cytoskeletal protein α–smooth muscle actin, are specialized cells that arise from resident fibroblasts, as well as epithelial and endothelial cells, adipocytes, and fibrocytes. Myofibroblasts synthesize collagens, tissue inhibitor of metalloproteinases (TIMPs), and other components of the ECM and are a major source of TGF-β during the fibrotic response. In normal wound healing, transient myofibroblast accumulation is detected in early granulation tissue, followed by their disappearance via apoptosis. The removal of myofibroblasts is a crucial step in normal wound healing. In contrast, in pathologic fibrogenesis, myofibroblasts persist in lesional tissue, resulting in stiff and contracted ECM characteristic of a chronic scar.

Residing within the walls of small blood vessels, pericytes are mesenchymal cells that are in intimate contact with the underlying endothelium and regulate vascular homeostasis. In patients with SSc, a marked increase in the microvascular pericyte compartment and increased expression of PDGF receptors have been reported. Activated pericytes can transdifferentiate into collagen-producing fibroblasts and myofibroblasts, thus linking microvascular injury and fibrosis.

Under certain conditions, epithelial cells can also undergo phenotypic transformation to fibroblasts. Epithelial-mesenchymal transition (EMT) plays a vital role during vertebrate embryonic development. Upon injury, epithelial cells lose characteristic markers and cell-cell adhesion and acquire fibroblast markers such as α–smooth muscle actin. Pathologic EMT is prominent in cancer and has also been implicated in renal fibrosis and idiopathic pulmonary fibrosis.[111] Similar to epithelial cells, upon fibrotic injury, vascular endothelial cells, mesothelial cells, and intradermal adipocytes can undergo a transition to myofibroblasts. These processes have been demonstrated in various forms of experimental fibrosis and might be implicated in SSc.

## Fibrocytes and Monocyte-Derived Mesenchymal Progenitor Cells

Fibrocytes are bone marrow–derived $CD34^+$ mesenchymal progenitor cells, normally present in small numbers in the peripheral blood, that can present antigen and synthesize collagen.[112] They express $CD14^+$ (a monocyte marker), as well as chemokine receptors (CCR3, CCR5, and CXCR4), which allows them to accumulate in specific tissues. The role for circulating fibrocytes and their tissue trafficking in the pathogenesis of fibrosis was established in animal models using neutralizing antibodies and in CXCR4-deficient mice. Mice with accelerated senescence have an increased number of circulating fibrocytes and show increased sensitivity to bleomycin-induced fibrosis. It is thought that in lesional tissue, fibrocytes undergo differentiation into activated myofibroblasts and contribute to the progression of fibrosis. Other studies have identified monocyte-derived multipotent mesenchymal progenitor cells in peripheral blood. Despite these experimental observations, the role of fibrocytes and other bone marrow–derived progenitor cells in SSc-associated fibrosis remains speculative.

# MOLECULAR DETERMINANTS OF FIBROSIS: TRANSFORMING GROWTH FACTOR-β

The expression of ECM genes is normally tightly controlled by paracrine/autocrine mediators, cell-cell contact, hypoxia, and contact with the surrounding ECM. Of the multitude of cytokines implicated in SSc (see Table 83-3), TGF-β is considered to be the master regulator of both physiologic fibrogenesis (wound healing and tissue repair) and pathologic fibrosis.[113]

A member of a large cytokine superfamily that also includes activin and bone morphogenetic proteins, TGF-β is secreted by platelets, monocytes/macrophages, DCs, and fibroblasts, and most cell types express surface receptors for TGF-β. TGF-β plays essential roles in tissue repair, angiogenesis, and immune regulation, and its dysregulation is implicated in cancer, fibrosis, and autoimmunity. Most cell types secrete TGF-β as a latent complex that is sequestered within the ECM and upon injury is converted to its biologically active form, which is capable of triggering cellular responses. Sequestration and activation of latent TGF-β is controlled in part by fibrillin-1 and is mediated by integrins, thrombospondins, αvβ6 integrin, and proteolytic enzymes. Because of its fundamental role in orchestrating fibrotic responses, TGF-β is considered a potential therapeutic target in SSc.[114]

**TABLE 83-4** Fibrogenic Activities of Transforming Growth Factor-β Relevant to Systemic Sclerosis

| |
|---|
| Recruits monocytes/macrophages |
| Stimulates synthesis of collagens, fibronectin, proteoglycans, elastin, tissue inhibitor of metalloproteinases; inhibits matrix metalloproteinases |
| Stimulates fibroblast proliferation, chemotaxis |
| Induces fibrogenic cytokine production: connective tissue growth factor; autoinduction; stimulates production of endothelin-1 |
| Stimulates generation of reactive oxygen species from Nox4 and mitochondria |
| Stimulates expression of TGF-β and PDGF surface receptors |
| Promotes fibroblast-myofibroblast differentiation, monocyte-fibrocyte differentiation |
| Promotes epithelial-mesenchymal and endothelial-mesenchymal transition; suppresses adipogenesis |
| Inhibits fibroblast and myofibroblast apoptosis |

PDGF, Platelet-derived growth factor.

## Cellular Signaling by Transforming Growth Factor-β: Canonical Smad Pathways

The type of response elicited by TGF-β is specific for the target cell and is highly context dependent. In mesenchymal cells, TGF-β acts as a potent inducer of fibrillar collagen synthesis and fibroblast proliferation, migration, and adhesion, and it suppresses the production of matrix-degrading metalloproteinases (Table 83-4). In endothelial and epithelial cells and adipocytes, TGF-β drives transdifferentiation into myofibroblasts. Binding of activated TGF-β to the type II TGF-β surface receptor triggers an intra-cellular signal transduction cascade that leads to the target gene expression. The evolutionarily conserved canonical TGF-β signal transduction pathway involves phosphorylation of the transmembrane type I TGF-β receptor, a serine-threonine kinase that in turn phosphorylates cytosolic Smads. Phosphorylated Smad2/3 form heterocomplexes with Smad4 and translocate into the nucleus, where they bind to consensus Smad-binding elements (SBEs) and recruit transcriptional cofactors such as the histone acetylase p300/CBP. Conserved SBE sequences are found in many TGF-β–inducible genes, including type I collagens, plasminogen activator inhibitor–1, α–smooth muscle actin, and connective tissue growth factor (CTGF). Signal transduction through the Smad pathway is tightly controlled by endogenous inhibitors such as Smad7 and bone morphogenetic protein and activin membrane-bound inhibitor.

## Noncanonical Transforming Growth Factor-β Signaling

Alternative non-Smad pathways also play a role in TGF-β signaling. Non-Smad TGF-β signaling involves protein kinases (c-Abl, ERK1/2, p38 and JNK, focal adhesion kinase [FAK], and TGF-β activated kinase [TAK1]); lipid kinases such as phosphatidylinositol 3′ kinase and its downstream target Akt; and the calcium-dependent phosphatase calcineurin. c-Abl is particularly relevant to SSc because this nonreceptor tyrosine kinase implicated in chronic myelogenous leukemia mediates profibrotic TGF-β and PDGF signal and is activated in SSc fibroblasts.[115] Imatinib, a small molecule inhibitor of c-Abl, reversed abnormal ECM gene expression in SSc fibroblasts and prevented skin fibrosis in mouse models of scleroderma.[116]

# CYTOKINES, GROWTH FACTORS, CHEMOKINES, AND LIPID MEDIATORS

Multiple paracrine/autocrine mediators of ECM accumulation and mesenchymal cell function show aberrant expression or activity in SSc. In addition to TGF-β, soluble mediators such as CTGF, PDGF, IL-4, IL-6, IL-13, adenosine, prostaglandin F2α, and lysophosphatidic acid (LPA1) play prominent roles in the pathogenesis of fibrosis and represent potential therapeutic targets.

## Connective Tissue Growth Factor/CCN2

CTGF is a cysteine-rich 40 kDa matricellular growth factor implicated in angiogenesis, wound healing, and development. Although it is undetectable in normal adults, CTGF is markedly elevated in fibrotic conditions. In SSc, serum CTGF levels correlate with the extent of skin and pulmonary fibrosis. The expression of CTGF can be induced in normal fibroblasts by TGF-β, IL-4, and VEGF, whereas TNF and prostacylins block stimulation. Transgenic mice overexpressing CTGF develop scleroderma-like diffuse skin fibrosis and microvascular disease.[117] Whereas CTGF exerts multiple profibrotic effects in normal fibroblasts, the cellular CTGF receptors and the mechanism of action underlying CTGF profibrotic responses remain incompletely characterized.

## Platelet-Derived Growth Factor

Platelet-derived growth factors (PDGFs) are disulfide-bonded heterodimeric proteins that act mainly on stromal cells and play key roles in wound healing. Originally isolated from platelets, PDGF isoforms are also secreted from macrophages, endothelial cells, and fibroblasts. By signaling via the α and β transmembrane receptors, PDGF acts as a potent fibroblast mitogen and chemoattractant and induces ROS generation and synthesis of collagen, fibronectin, and proteoglycans, as well as the secretion of TGF-β1, MCP-1, and IL-6. In transgenic mice expressing a constitutively active PDGF-α receptor, fibrosis develops in the skin and multiple organs.[118] Lesional skin fibroblasts from patients with SSc show elevated PDGF and PDGF-β receptor expression,[119] and PDGF levels are increased in SSc bronchoalveolar lavage fluid. Some patients with SSc appear to have functional circulating antibodies to the PDGF receptor that can induce fibroblast activation and ROS generation; however, they have also been detected in patients with graft-versus-host disease, and their significance in pathogenesis remains to be established.

## Developmental Pathways: Wnt and Notch

Wnt and Notch are involved in embryonic developmental pathways that appear to be deregulated in fibrosis and SSc. The Wnts comprise a family of poorly soluble glycoproteins with dual roles in cell-cell adhesion and transcriptional

regulation. The Wnts have essential roles in morphogenesis, stem cell homeostasis, and cell fate determination, and abnormal Wnt signaling is implicated in cancer, as well as rheumatoid arthritis and osteoarthritis, osteoporosis, PAH, and aging. Intra-cellular Wnt signaling is mediated via both canonical (β-catenin) and noncanonical pathways, with extensive cross-talk with TGF-β signaling. Transgenic mice overexpressing Wnt10b or a constitutively active mutant β-catenin develop exuberant wound healing and tissue fibrosis.[120] Lungs from patients with idiopathic pulmonary fibrosis show increased nuclear β-catenin accumulation at fibrotic foci. Genomewide transcriptome analysis of SSc skin biopsies shows elevated expression of Wnt ligands, receptors, and targets. Constitutive Wnt-β-catenin signaling in SSc appears to be due to epigenetic silencing of endogenous Wnt inhibitors such as DKK1.

Notch, the transmembrane receptor for Jagged, has a fundamental role in embryonic development, wound healing, and tissue repair. Notch signaling regulates endothelial cell and fibroblast responses, including myofibroblast differentiation. Notch signaling was markedly enhanced in the skin and lungs in a mouse model of scleroderma. ADAM-17 is a proteinase induced by TGF-β and ROS that initiates Notch signal transduction, and its activity is elevated in SSc skin biopsies.[121]

## Interleukins

Members of the IL-1 family are secreted from multiple cell types. A recent study showed that SSc epidermal keratinocytes secreted IL-1α, and their co-culture with normal skin fibroblasts resulted in fibroblast activation and myofibroblast differentiation that was mediated by IL-1α. The Th2 cytokine IL-4 stimulates fibroblast proliferation, chemotaxis, collagen synthesis, and production of TGF-β, CTGF, and TIMP. Serum levels of IL-4 are elevated in SSc, and the number of IL-4–producing T cells is increased in both peripheral blood and skin. IL-6, which is produced by monocytes, B and T cells, fibroblasts, and endothelial cells, directly stimulates collagen and TIMP-1 synthesis in fibroblasts and promotes a Th2-polarized immune response. The biologic activities of IL-6 are mediated via the Janus kinase (JAK)–signal transducer and activator of transcription (STAT) intra-cellular signaling pathway that is shared with other cytokines. Serum levels of IL-6 are elevated in SSc and correlate with the severity of skin involvement. Another Th2 cytokine, IL-13, is implicated in asthma and a variety of fibrotic conditions. IL-13 has profibrotic effects that are both indirect via stimulation of TGF-β production by macrophages and direct via stimulation of fibroblast proliferation and collagen synthesis. Serum levels of IL-13 are elevated in persons with SSc.

## Chemokines

Chemokines represent a superfamily of more than 40 low-molecular-weight soluble mediators that were originally identified based on their chemotactic effects on leukocytes but also have a broad range of cellular targets and biologic activities, including regulation of angiogenesis, wound healing, and fibrosis. The CC chemokine MCP-1 stimulates collagen production directly, as well as through induction of endogenous TGF-β. Serum and bronchoalveolar lavage fluid levels of MCP-1, along with those of macrophage inflammatory protein (MIP)-1α, IL-8 (CXCL8), and CCL18, are elevated in persons with SSc and correlate with the severity of skin fibrosis. Mononuclear cells and dermal fibroblasts from patients with SSc spontaneously produce these chemokines, and lesional SSc fibroblasts show constitutively high expression of the MCP-1 receptor CCR2. Because MCP-1 drives a Th2 response, the MCP-1–CCR2 axis is thought to play a major role in the pathogenesis of SSc by amplifying collagen stimulation and promoting Th2 cytokine production. Significantly, MCP-1 null mice are resistant to the development of fibrosis induced by bleomycin.[122] A global survey of chemokine expression in SSc skin revealed enhanced levels of MCP-1, CCL19, CXCL13, and MCP-3, particularly in patients with early-stage disease.[123]

Additional chemokines overexpressed in lesional tissue or serum in patients with SSc or in animal models of scleroderma include regulated upon activation, normal T cell expressed and secreted (RANTES) and pulmonary and activation-regulated chemokine (PARC; CC chemokines), as well as MIP-2 and fractalkine (CXC chemokines). Insulin-like growth factor binding protein-1 (IGFBP-1) stimulates collagen synthesis and fibroblast proliferation and induces TGF-β. Patients with SSc have elevated levels of IGF-1 in the bronchoalveolar lavage fluid. Expression of IGFBP-3 is markedly elevated in SSc fibroblasts. Adenovirus-mediated overexpression of IGFBP-5 caused chronic scleroderma-like fibrosis in mice.[124]

## Angiotensin II

Angiotensin II is a vasoconstricting peptide hormone generated via proteolytic cleavage of angiotensin I by the angiotensin-converting enzyme in endothelial cells. The renin-angiotensin system is implicated in pathologic fibrosis in the heart, liver, lung, and kidneys. Serum levels of angiotensin II are elevated in patients with difuse SSc (dcSSc), and many patients have functional antibodies targeting the angiotensin II type 1 receptor. Moreover, angiotensin II is elevated in SSc dermal fibroblasts. In cultured fibroblasts, angiotensin II promotes collagen synthesis and TGF-β production. Chronic subcutaneous administration of angiotensin II induces scleroderma-like skin fibrosis and inflammation in mice, whereas treatment with an inhibitor of the angiotensin II type I receptor ameliorates fibrosis in experimental mouse models.

## Bioactive Lipids

Bioactive lipids are potent modulators of fibroblast function and tissue repair. Although some prostanoids inhibit fibrotic responses, prostaglandin F ($PGF_{2\alpha}$) stimulates collagen production and fibroblast proliferation and is elevated in patients with pulmonary fibrosis and can induce fibrotic responses.[125] Mice with targeted deletion of the PGF receptor are protected from bleomycin-induced pulmonary fibrosis. LPA, generated from membrane phospholipids via hydrolysis, exerts multiple biologic activities through G protein–coupled transmembrane receptors. LPA was shown to induce fibroblast chemotaxis and CTGF

production. A recent study indicated that LPA induces αvβ6 integrin-mediated TGF-β activation in epithelial cells, contributing to sustained autocrine TGF-β signaling.[126] LPA levels are elevated in the lungs of patients with pulmonary fibrosis. Moreover, LPA1 knockout mice are protected from bleomycin-induced skin and lung fibrosis.

### Regulation of Fibroblast Function via Innate Immune Signaling: Toll-like Receptors and the Inflammasome

The presence of a type I IFN signature in SSc leukocytes, and genetic studies showing an association of innate immunity genes with SSc, support the role of TLR-mediated innate immune responses in pathogenesis. All members of the TLR family are expressed by normal fibroblasts. Activation of TLR4 by its ligand LPS plays a critical role in liver fibrosis, with sensitization to TGF-β as the underlying mechanism. In SSc, tissue fibroblast TLRs are activated by endogenous TLR ligands. These so-called *damage-associated molecular patterns* are generated by tissue injury, autoimmunity, and oxidative stress. Endogenous TLR ligands potentially implicated in SSc belong to three categories: ECM-derived molecules such as hyaluronan and its small-molecular-weight degradation products, tenascin C, alternatively spliced extra domain A (EDA) fibronectin ($Fn^{EDA}$), and biglycan; cellular stress proteins (alarmins) such as HMGB1 and Hsp60; and nucleic acids and immune complexes released from damaged or necrotic cells. Levels of TLR3 and TLR4 are elevated in SSc skin and lung biopsies and correlate with disease progression. The TLR3 ligand poly(I:C) causes dramatic induction of type I IFN, IL-6, and other inflammatory cytokines, as well as ECM molecules, in normal fibroblasts. The damage-associated molecules $Fn^{EDA}$ and tenascin C are alternatively spliced isoforms on normal ECM proteins that are generated during tissue injury, accumulate to high levels in lesional SSc skin and lung, and function as endogenous TLR4 ligands to elicit profibrotic responses.[127] These observations suggest that in SSc, fibroblast TLR signaling initiated by damage-associated endogenous TLR ligands in SSc converts self-limited regenerative tissue repair into an aberrant and intractable fibrotic scar.

Intra-cellular innate immune sensors include NOD-like receptors (NLRs), retinoic acid inducible gene I (RIG-I), and NALP3. They respond to cytosolic nucleic acids, damage-associated endogenous molecules, oxidative stress, and environmental signals such as silica, bleomycin, and gadolinium. Once activated, these sensors facilitate inflammasome assembly with activation of caspase-1 and secretion of proIL-1β and IL-18. *NLRP1* is identified as a susceptibility gene for SSc and associated pulmonary fibrosis. Inflammasome activation and IL-1β play an important role in experimental mouse fibrosis and might be involved in SSc as well.[128]

### Negative Regulation of Extra-cellular Matrix Accumulation

To prevent excessive scarring after injury, redundant biologic mechanisms have evolved. Fibroblasts are equipped with endogenous molecules that repress ECM gene expression and TGF-β stimulation. For example, Smad7 is an inhibitory Smad that blocks TGF-β signal transduction by accelerating ubiquitin-mediated TGF-β receptor degradation. Functional impairment of Smad7 was demonstrated in SSc fibroblasts. Other cell-intrinsic endogenous repressors of collagen synthesis include the transcription factors Sp3, Fli-1, p53, Ras, Nrf2, and the nuclear hormone receptor, peroxisome proliferator-activated receptor-γ (PPAR-γ), and their impaired expression, induction, or function might contribute to the failure to limit fibroblast activation in SSc.

### Interferon-γ

IFN-γ, the prototypical Th1 cytokine, is a major negative regulator of fibroblast activation. IFN-γ represses collagen gene expression and abrogates stimulation induced by TGF-β.[129] IFN-γ is also a potent inhibitor of fibroblast proliferation, fibroblast-mediated matrix contraction, and myofibroblast transdifferentiation. Significantly, some studies have shown that fibroblasts from patients with SSc are relatively resistant to the inhibitory effects of IFN-γ. Clinical trials of IFN-γ in SSc have demonstrated a modest and inconsistent improvement in skin fibrosis.

### Peroxisome Proliferator-Activated Receptor-γ

PPAR-γ is an intra-cellular molecule that modulates TGF-β signaling and mesenchymal cell plasticity and is functionally associated with fibrosis. Originally identified as a key regulator of adipogenesis, glucose homeostasis, and lipid metabolism, PPAR-γ has a dual function as both a nuclear hormone receptor and ligand-inducible transcription factor. Multiple lipid moieties and electrophilic prostanoids such as 15d-prostaglandin $J_2$ (15d-$PGJ_2$) can serve as endogenous ligands for PPAR-γ. The thiazolidinedione class of insulin-sensitizing drugs, including rosiglitazone and pioglitazone, are potent pharmacologic PPAR-γ agonists. PPAR-γ modulates vascular and immune processes, and abnormal PPAR-γ function is implicated in lipodystrophy, atherosclerosis, PAH, and inflammatory diseases. In fibroblasts, 15d-$PGJ_2$ or pharmacologic PPAR-γ ligands abrogated TGF-β–induced collagen production, myofibroblast transdifferentiation, EMT, and other Smad3-dependent responses. Both the expression and the activity of PPAR-γ are impaired in patients with dcSSc.[130] Of note, multiple factors in SSc pathogenesis including TGF-β, Wnt ligands, IL-13, hypoxia, LPA, and CTGF potently inhibit PPAR-γ function.

## SCLERODERMA FIBROBLAST

Fibroblasts explanted from SSc skin or lungs display an abnormal activated phenotype that persists during their serial passage in vitro, indicating autonomous alteration in cell function. The "SSc phenotype" is characterized by enhanced ECM synthesis, secretion of profibrotic cytokines and chemokines, insensitivity to IFN-γ and other inhibitory signals, and resistance to apoptosis. Moreover, SSc fibroblasts show spontaneous myofibroblast differentiation, in part because of constitutive activation of the FAK focal adhesion kinase. It remains unsettled whether the activated

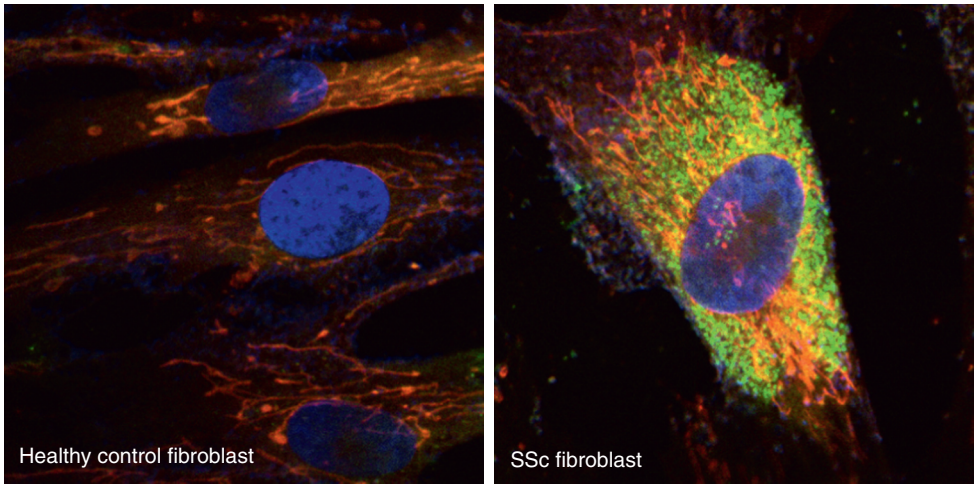

**Figure 83-11** Spontaneous reactive oxygen species (ROS) production by systemic sclerosis (SSc) skin fibroblasts. Skin fibroblasts from healthy control subjects and patients with SSc were incubated in media with MitoSOX Red and CellROX Green probes to measure mitochondrial or cytosolic ROS generation. Nuclei are stained with 4′,6-diamidino-2-phenylindole (DAPI; *blue color*). Note the marked increase in both cytosolic *(red)* and mitochondrial *(green)* ROS accumulation in SSc fibroblasts. Representative confocal images. *(Courtesy Jun Wei, PhD.)*

SSc fibroblast phenotype represents an enduring intrinsic cell-autonomous abnormality or activation by exogenous stimuli in the fibrotic milieu.

Numerous molecules involved in intra-cellular signal transduction are abnormally expressed or constitutively activated in SSc fibroblasts. The list includes protein kinase C, Smad3, FAK, Akt, SIRT1, Egr-1, p300, and c-Abl. Elevated expression of Bcl-2 and Akt in SSc fibroblasts may play a role in their relative resistance to apoptosis. Spontaneous ROS generation contributes to the sustained activation of SSc fibroblasts in a self-amplifying loop (Figure 83-11). Because most characteristics of the SSc fibroblasts can be induced by treating normal fibroblasts with TGF-β, the SSc phenotype could contribute to autocrine TGF-β signaling. The levels of TGF-β receptors are elevated on SSc fibroblasts, which might sensitize these cells to endogenously produced TGF-β or to low levels of environmental TGF-β. Furthermore, SSc fibroblasts express thrombospondin and αvβ3 integrins, which activate latent TGF-β at the cell surface. Consistent with the autocrine TGF-β hypothesis, SSc fibroblasts show constitutive TGF-β signaling with elevated Smad3 activation and interaction with p300/CBP. Other studies demonstrate defective expression or function of endogenous suppressors of TGF-β signaling and ECM production such as Smad7, Fli1, adiponectin, and NF4a1, suggesting that failure to terminate fibroblast activation may represent a fundamental defect in SSc.

Autocrine TGF-β activation of fibroblasts cannot fully account for all of the phenotypic hallmarks of SSc fibroblasts, indicating that both Smad-independent TGF-β signaling mechanisms, as well as non-TGF-β–mediated activation events, underlie the induction or maintenance of the SSc phenotype. The autonomous SSc phenotype also could result from abnormal integrin-mediated signaling from the surrounding ECM. Moreover, epigenetic alterations in SSc fibroblasts are associated with persistent and heritable fibroblast dysfunction. For example, silencing the *FLI1* gene, an important endogenous negative regulator of collagen gene expression, by DNA methylation or chromatin histone deacetylation suppresses its expression in fibroblasts from lesional skin, which increases collagen synthesis.

## CONCLUSION

Novel insights from genetic association studies, whole genome-scale analysis of altered gene expression and the role of epigenetic modifications, and phenotyping of circulating and tissue-resident cell types have identified fundamental alterations in immune, wound healing, and developmental responses that underlie the clinical manifestations of SSc. At the same time, these unbiased high-throughput studies also highlight the surprising degree of molecular heterogeneity that is a hallmark of SSc. Of interest, the genes associated with increased risk in SSc are predominantly those that are involved in inflammation, innate immunity, and immune cell signaling and show pervasive overlap with genes associated with SLE, psoriasis, and other autoimmune conditions. These observations suggest that immune dysregulation likely plays a primary and fundamental role in the pathogenesis of SSc.

Nonetheless, it remains unknown why autoimmune diseases with significant shared genetic risk factors, such as SSc and SLE, show such diverse and nonoverlapping clinical and pathologic manifestations, natural histories, responses to immunomodulatory therapies, and disease outcomes. The precise environmental exposures important in SSc, and how they elicit epigenetic modifications that contribute to the persistence of autoimmune and fibrotic processes, are beginning to be characterized. These insights are likely to make significant contributions toward an improved understanding of disease pathogenesis, identification of novel biomarkers of diseases activity and subtype, and discovery and validation of novel therapeutic targets. Although no effective disease-modifying therapies are currently approved for SSc, an improved understanding of pathogenesis is opening the door for the evaluation of novel and selective immunomodulatory, antifibrotic agents and epigenetic modifiers that are precision-targeted for the treatment of disease subsets in SSc.

CHAPTER 84

# Clinical Features and Treatment of Scleroderma

Fredrick M. Wigley • Francesco Boin

**KEY POINTS**

- **Systemic sclerosis is a multisystem connective tissue disease affecting the skin and internal organs.**
- **The disease process is characterized by chronic inflammation with variable degrees of collagen accumulation (fibrosis) in affected tissues and obliterative vasculopathy of the peripheral and visceral vasculature.**
- **Scleroderma can be associated with high morbidity and mortality in certain subsets, particularly when the lungs, heart, gastrointestinal tract, and kidneys are involved.**
- **Effective management of organ-specific disease manifestations is recommended, although no disease-modifying therapy is yet available.**

Some people believe that the first description of systemic sclerosis (scleroderma) was put forth in 1753 by Cario Curzio (Naples, Italy).[1] However, a careful review of the reported case suggests that the diagnosis was really *scleroedema* because of the distribution of the skin changes and the fact that the 17-year-old female improved with bloodletting, warm milk, and small doses of quicksilver. In 1836, Fantonetti (1791-l877), a Milanese physician, became the first person to use the word *scleroderma* to designate a skin disease in an adult. However, it is likely that this patient too had scleroedema. The first convincing case of scleroderma was reported in 1842; several acceptable cases were then published before 1847, when Gintrac used the term *sclerodermie*, establishing this condition as a specific clinical entity.[2] By 1860, numerous cases had been reported, and articles reviewing the disease were published. Maurice Raynaud (1834-1881) described a patient with *sclerodermie* and cold-induced "asphyxie locale," which was the first description of Raynaud's phenomenon (RP) in a person with scleroderma. Sir William Osler described scleroderma while at Johns Hopkins Hospital between 1891 and 1897.[3] Osler recognized the systemic nature of the disease and was so impressed with the severity of scleroderma that he wrote:

> In its more aggravated forms, diffuse scleroderma is one of the most terrible of all human ills. Like Tithonus, to "whither slowly," and like him to be "beaten down and marred and wasted" until one is literally a mummy, encased in an ever-shrinking, slowly contracting skin of steel, is a fate not pictured in any tragedy, ancient or modern.

Matsui (Japan, 1924) emphasized the importance of visceral involvement as part of scleroderma based on several autopsies. Goetz[4] (Capetown, 1945) further confirmed the multisystem involvement and suggested that the disease be named *progressive systemic sclerosis*.

The concept of subtypes of scleroderma was introduced in 1964, when Winterbauer[5] reported cases with the CRST (calcinosis, Raynaud's phenomenon, sclerodactyly, and telangiectasia) syndrome. A similar group of patients was reported in 1920, and the condition was named after the authors—the Thiberge-Weissenbach syndrome. Velayos and colleagues[6] recognized that esophageal dysmotility was common in these patients, and for this reason the term "CREST syndrome" was introduced.

In 1969, 58 autopsy cases of scleroderma were compared with matched control subjects.[7] The organs found to be frequently and significantly affected by this disease were the skin, gastrointestinal (GI) tract, lungs, kidneys, skeletal muscle, and pericardium. This report first described the systemic nature of scleroderma vascular disease with findings of both kidney and lung arterial changes. In 1979, Rodnan et al.[8] introduced a clinical method to evaluate the extent of skin disease. Steen and Medsger with others conducted extensive surveys of large populations of patients with scleroderma, defining the clinical course and specific subtypes of disease. In the 1970s, an expert subcommittee established diagnostic criteria, and Leroy and colleagues suggested the classification of two major subsets of disease defined by skin involvement: *limited* and *diffuse*. Later, work by several investigators led to the recognition that scleroderma has an autoimmune basis and that the occurrence of specific autoantibodies is associated with subtypes of disease and is useful in predicting disease course. In 2001, Leroy and Medsger[9] proposed that the presence of RP, abnormal nail-fold capillaries, and positive serologic findings for scleroderma-specific autoantibodies would be adequate for the diagnosis of *early* disease. New classification criteria have recently been proposed by a collaborative effort between the American College of Rheumatology (ACR) and the European League Against Rheumatism (EULAR), significantly improving the sensitivity and specificity of the 1980 ACR criteria, particularly for patients with early/limited disease.[10]

Scientific work in the modern era has revealed details regarding the pathogenesis of the disease and has led to the recognition that scleroderma is a complex polygenetic autoimmune disease associated with a unique disease process involving tissue fibrosis. Although a drug with clear disease-modifying properties and the ability to fully control the

underlying disease process has yet to be discovered, major progress has been made in managing specific organ disease. The discovery that an angiotensin-converting enzyme (ACE) inhibitor could reverse the scleroderma renal crisis in the 1970s has changed the course of kidney disease in people with scleroderma and has improved the survival of patients. Current therapies for GI, cardiac, pulmonary, vascular, and interstitial lung disease (ILD) have improved quality of life and survival.

## EPIDEMIOLOGY

### Incidence and Prevalence

Scleroderma is a rare disease with an estimated incidence of approximately 18 to 20 cases per million population per year and a prevalence of 100 to 300 cases per million population. Reported rates vary based on the method of ascertainment, the population under study, and the definition of disease. Scleroderma is found in all races and in various geographic areas, but the prevalence and severity of disease vary among different racial and ethnic groups. The prevalence of scleroderma appears to be greater in the United States, where it has been estimated at 24.2 per 100,000, than in Europe, where recent studies in Iceland, England, France, and Greece have estimated rates ranging from 7.1 to 15.8 per 100,000.[11] In Australia, estimates are similar to those in the United States, whereas in Asia (i.e., Japan and Taiwan), lower prevalences (3.8 to 5.6 per 100,000) similar to those in Europe have been reported.[12,13] The highest scleroderma prevalence is reported among Choctaw Native Americans, in whom the disease appears to be more severe than in other populations.[14] Several surveys in the United States show that African-Americans have a higher age-specific incidence rate and experience more severe disease than do white persons.[15] Occurrence is not different from urban to rural areas. Occasional reports have described unusually large numbers of cases of scleroderma observed in restricted geographic regions, suggesting nonrandom distribution of the disease. For example, in a rural area in the province of Rome, a geographic cluster of scleroderma and disease with related features was reported, suggesting prevalence 1000 times greater than expected.[16] Likewise, a study in the United Kingdom reported a higher prevalence of scleroderma in three geographic areas clustered near airports compared with other areas of the United Kingdom.[17]

The average age at onset is between 35 and 50 years, and the disease is more common among women (3 to 7:1 female-to-male ratio). Disease onset in elderly individuals is well described; it is uncommon for the disease to become manifest before the age of 25 years. Older age at onset is associated with increased risk for multisystem disease and, in particular, pulmonary arterial hypertension (PAH). A progressive increase in the incidence of scleroderma has been noted with increasing age. During the period from 1963 to 1982, in Pittsburgh, Pennsylvania, the highest rates of scleroderma were observed between the ages of 45 and 54 years in black women and between the ages of 55 and 64 years in white women.[18] Younger age at disease diagnosis among black women compared with white women was reported in Detroit, Michigan.[11]

### Survival

Mortality among patients with scleroderma is high, with most deaths being attributed directly to disease manifestations.[19] In fact, the prognosis in scleroderma is highly variable, and survival is influenced by disease subtype, degree of internal organ involvement, and comorbid conditions. Factors associated with poor prognosis include diffuse skin disease, the presence of pulmonary disease (particularly PAH), renal or cardiac involvement, severe GI failure, multisystem disease, older age at disease onset, and the presence of anemia. A worse disease course and higher mortality have also been reported in African-American patients.[20,21] The standardized mortality rate (SMR) is the measure used to assess the relative mortality of a disease in comparison with the general population. Surveys of patients with scleroderma report an SMR from 1.46 to 7.1. A survey found that among 284 patients with scleroderma who died, the median disease duration as estimated from the onset of RP until death was 7.1 years for patients with diffuse skin disease and 15.0 years for patients with limited skin disease. Among non–scleroderma-related causes of death are, as expected, infection, malignancy, and cardiovascular events. Premature atherosclerosis has been implicated as the cause of early death in other inflammatory autoimmune diseases. Recent studies indicate that scleroderma also is independently associated with a higher risk of developing complications from macroscopic coronary artery or cerebrovascular involvement beyond that expected in the general population.[22-24]

Several studies suggest that the main cause of death has changed over time. Improved survival in recent years is thought to be to the result of more effective treatments for specific organ-based complications. It seems clear that the natural history of scleroderma renal complications has changed as a result of the use of ACE inhibitors for renal crisis. Historically, patients with scleroderma renal crisis had a 1-year survival rate of less than 15%.[25] Recent case-control studies conducted after the introduction of ACE inhibitors suggest a 1-year survival rate that is greater than an 85%. Pharmacologic prevention and treatment of ILD and PAH are thought to have an impact. Cohort studies have demonstrated improved overall survival among patients with scleroderma. At one scleroderma center, the 10-year survival rate from the time of disease diagnosis improved from 54% in the 1972-1981 group to 66% in the 1982-1991 group.[26] In another survey it was found that the 5-year survival rate among patients with diffuse cutaneous scleroderma improved from 69% in 1990-1993 to 84% in 2000-2003 ($P = 0.018$), whereas 5-year survival among patients with limited cutaneous scleroderma remained unchanged at 93% and 91%, respectively.[27]

### Environmental Exposures

Geographic clustering of scleroderma cases suggests that environmental exposure may be responsible for the disease, but definitive proof is still lacking. Epidemics of scleroderma-like illness after exposure to dietary (L-tryptophan or adulterated rapeseed oil), occupational (silica), or pharmacologic (e.g., bleomycin and gadolinium-based contrast media) toxins support the idea that environmental exposure can trigger a fibrotic disease. Typical scleroderma is found among

coal miners and workers exposed to silica, particularly male workers. A meta-analysis of the risk of silica exposure found that the combined estimator of relative risk was 1.03 (95% confidence interval [CI], 0.74 to 1.44) in females and 3.02 (95% CI, 1.24 to 7.35) in males.[28] Although occupational exposure to solvents (e.g., paint thinner or removers, mineral spirits, trichloroethylene, trichloroethane, perchloroethane, gasoline, aliphatic hydrocarbons, halogenated hydrocarbons, and BTX solvents containing benzene, toluene, or xylene) or polyvinyl chloride is reported to be associated with scleroderma, the role of these agents in causing disease is controversial and remains unproven. Likewise, case reports have suggested that the silicone present in breast implants has triggered scleroderma, but large epidemiologic surveys have not found a greater incidence of scleroderma than expected in women with breast implants or exposure to silicone. Drugs implicated as potentially causative for systemic sclerosis (SSc)-like illnesses include bleomycin, pentazocine, and cocaine. Interestingly, cigarette smoking is not associated with an increased risk for scleroderma.[29] Actually, a study conducted in Canada indicated that smoking was associated with a decreased severity of scleroderma skin disease, although the mechanisms for this finding are unclear.[30]

## CLINICAL FEATURES

### Diagnostic Criteria

A subcommittee of the ACR established the "preliminary" diagnostic criteria in 1980 based on a consensus of experts who evaluated a multicenter survey of patients with scleroderma compared with other patient groups (Table 84-1).[31] The purpose of these criteria was to provide diagnostic certainty and consistency for research and other documentary exercises. Consequently, despite a high specificity, their sensitivity was poor, and patients with early stage scleroderma and 20% of those with limited cutaneous disease did not meet these criteria.[9] Since then, knowledge about the prognostic relevance of scleroderma-specific autoantibodies has significantly improved, and the use of nail-fold capillaroscopy has become a widely accepted, reliable diagnostic tool, supporting the recommendation by some experts to revise the 1980 classification criteria to be more inclusive of patients with early disease manifestations.[32,33] For this reason, the ACR and EULAR established a joint committee to define new classification criteria, which were published in 2013 (Table 84-2).[10] The single finding of thickening of the skin proximal to the metacarpophalangeal (MCP) joints of the hands remains a criterion that alone is sufficient to classify a patient as having scleroderma. If skin thickening is found only distal to the MCP joints, then a point system is applied based on the presence of seven other specific manifestations. These manifestations include skin thickening of the fingers, fingertip lesions, telangiectasias, abnormal nail-fold capillaries, PAH and/or ILD, RP, and scleroderma-related autoantibodies. Patients with a combined score of 9 or more points are classified as having scleroderma. The new criteria have a specificity of 0.91 and a sensitivity of 0.92, which overall represent a much better performance compared with the previous criteria. Nonetheless, patients without skin thickening but with the presence of RP, abnormal nail-fold capillaries, and positive scleroderma-specific autoantibodies still do not meet the 2013 ACR/EULAR criteria. Large longitudinal surveys confirm that in a high percentage of patients with this "early" phenotype, scleroderma develops within a 2- to 4-year period of follow-up.[32,34] Therefore, although classification criteria are useful in defining cases for research purposes, the clinician needs to take into account subtle features of the disease to make an early diagnosis and institute prompt management. Most experts would accept the finding of three of the five features of the CREST syndrome (*c*alcinosis, *R*aynaud's phenomenon, *e*sophageal dysfunction, *s*clerodactyly, and *t*elangiectasias) to make a clinical diagnosis of scleroderma. In clinical practice, one needs to recognize that although some patients do not experience skin changes, they nonetheless have systemic disease (systemic sclerosis sine scleroderma), and that many patients will present with only partial expression of the disease (e.g., RP with nail-fold changes only), with well-defined disease developing later. Experts argue that patients who have partial expression, especially when a specific scleroderma-related autoantibody is present, should be considered to have a diagnosis of scleroderma and be treated accordingly.

**TABLE 84-1** Establishing a Diagnosis of Scleroderma

| |
|---|
| **1980 ACR Criteria** |
| Must have (a) or two of (b), (c), or (d): |
| a. Proximal SSc (proximal to MCPs/MTPs) |
| b. Digital pits |
| c. Sclerodactyly |
| d. Pulmonary fibrosis (chest radiograph; HRCT) |
| **CREST Criteria** |
| Must have three of the five features: |
| a. Calcinosis |
| b. Raynaud's phenomenon |
| c. Esophageal dysmotility |
| d. Sclerodactyly |
| e. Telangiectasias |
| **Minor Criteria**[*†] |
| Must have all three: |
| a. Definite Raynaud's phenomenon |
| b. Abnormal capillary loops |
| c. Specific scleroderma autoantibody |

*Some experts continue to classify patients with minor criteria only as undifferentiated connective disease with scleroderma features.

†Proximal areas include the face. Autoantibody includes anticentromere, antitopoisomerase 1 (Scl-70), and anti-RNA polymerase III.

ACR, American College of Rheumatology; CREST, calcinosis, Raynaud's phenomenon, esophageal dysfunction, sclerodactyly, telangiectasias; HRCT, high-resolution computed tomography; MCPs, metacarpophalangeal joints; MTPs, metatarsophalangeal joints; SSc, systemic sclerosis.

### Classification and Clinical Subsets

The scleroderma disease process is complex and its clinical expression is very heterogeneous, such that the disease is expressed in several distinct clinical phenotypes. Classifying patients into subtypes is useful both for investigative purposes and for clinical practice. A specific subtype can define increased risk for internal organ involvement and overall prognosis. The traditional way to classify patients is by the

**TABLE 84-2** American College of Rheumatology/European League against Rheumatism Classification Criteria for the Classification of Systemic Sclerosis

| Item | Sub-item(s) | Weight/Score |
|---|---|---|
| Skin thickening of the fingers of both hands extending proximal to the metacarpophalangeal joints *(sufficient criterion)* | — | 9 |
| Skin thickening of the fingers *(only count the higher score)* | Puffy fingers<br>Sclerodactyly of the fingers (distal to the MCPs but proximal to the proximal interphalangeal joints) | 2<br>4 |
| Fingertip lesions *(only count the higher score)* | Digital tip ulcers<br>Fingertip pitting scars | 2<br>3 |
| Telangiectasia | — | 2 |
| Abnormal nailfold capillaries | — | 2 |
| Pulmonary arterial hypertension and/or interstitial lung disease *(maximum score 2)* | Pulmonary arterial hypertension<br>Interstitial lung disease | 2<br>2 |
| Raynaud's phenomenon | — | 3 |
| SSc-related autoantibodies *(maximum score is 3)* | ACA<br>Scl-70<br>RNA Pol | 3 |

*The total score is determined by adding the maximum weight (score) in each category. Patients with a total score of ≥9 are classified as having definite SSc.

ACA, Anticentromere; MCPs, metacarpophalangeal joints; RNA Pol, anti-RNA polymerase III; Scl-70, antitopoisomerase 1; SSc, systemic sclerosis.

Modified from van den Hoogen F, Khanna D, Fransen J, et al: 2013 classification criteria for systemic sclerosis: an American College of Rheumatology/European League against Rheumatism collaborative initiative. *Arthritis Rheum* 65:2737–2747, 2013.

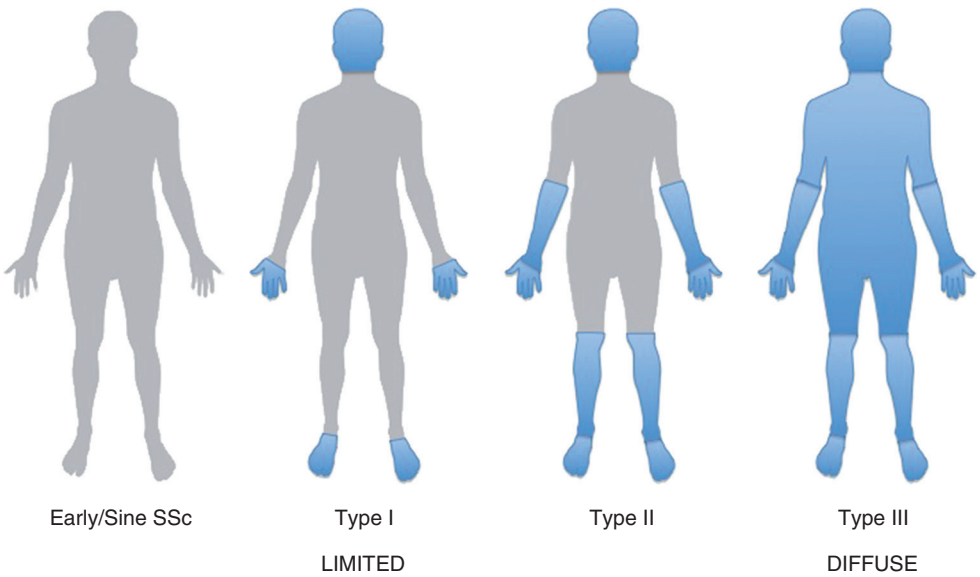

**Figure 84-1** Classification of scleroderma and clinical subsets. Most experts classify scleroderma into two major groups: limited and diffuse. Limited includes patients with no skin changes (early scleroderma or systemic sclerosis "sine" scleroderma), and type I (fibrosis limited to the digits) or type II (fibrosis up to the elbows and the knees). Diffuse or type III have more proximal limb or truncal involvement (the face is excluded). SSc, Systemic sclerosis.

degree of skin thickening as determined by physical examination. The skin is scored by pinching a fold and deciding whether it is abnormally thickened because of the scleroderma process. A committee of experts decided by consensus that two major groups of patients can be identified based on the distribution of skin changes and associated clinical and laboratory outcomes (Figure 84-1).[35] Patients are considered to have *diffuse skin disease* if skin changes are found proximal to the elbows and/or knees or on the trunk, excluding the face. These patients tend to have higher risk of multisystem disease and poor survival. Patients are considered to have *limited disease* if skin changes occur distal to the elbows and/or knees and not on the trunk. Facial skin thickening can be present in the limited group. Some clinicians argue that the term *CREST syndrome* should be eliminated and that these patients should be classified in the

limited skin group. Others believe that the CREST syndrome is a unique subtype within the broader group of limited skin diseases with a distinct disease course.

Another less popular classification system divides patients into three groups based on skin changes: limited (fingers only), intermediate (skin on the elbows or knees), and diffuse (skin above the elbows and/or knees and/or trunk). Studies using this classification have found that the intermediate group had distinct clinical outcomes, including an intermediate survival statistic between limited (best) and diffuse (worse).[36] A subtype of disease with absence of skin fibrosis has been recognized and is referred to as *scleroderma sine scleroderma*. Serologic studies have shown that the presence of specific autoantibodies predicts clinical features of the disease, suggesting that the classification might be based on the autoantibody type (see the "Natural History of Disease" section). Patients with early or partial expression of the disease (e.g., RP alone with nail-fold capillary loop abnormalities) are often diagnosed as having undifferentiated connective tissue disease. Clear features of scleroderma will develop in about 20% of these patients, usually within 2 to 4 years of follow-up.[34]

Patients with scleroderma often have features of another rheumatic or autoimmune disease. These patients are considered to have an *overlap syndrome*. The most common overlap syndromes are polyarthritis, myositis, sicca complex, and hypothyroidism. Less common are primary biliary cirrhosis, autoimmune hepatitis, vasculitis, rheumatoid arthritis, and anti-neutrophil cytoplasm antibody (ANCA)-associated pauci-immune glomerulonephritis. Mixed connective tissue disease is an overlap syndrome with features of scleroderma, polymyositis, lupus-like rashes, and rheumatoid-like polyarthritis.

### Natural History of Disease

The natural history of scleroderma varies a great deal depending on the specific subtype of disease established in a patient. Scleroderma tends to be a chronic monophasic illness, unlike systemic lupus erythematosus, which is characterized by quiescence interrupted by sudden disease flares. The pattern of the disease and the degree or type of internal organ involvement are variable but generally can be predicted by the extent of skin affected. Internal organ disease is more severe in patients with the diffuse skin type than in those with limited scleroderma. The disease course is usually indolent in patients with sclerodactyly alone. In these patients, years pass from onset of RP before obvious organ dysfunction manifests, although explosive multisystem disease can emerge rapidly over several months in patients with widespread skin changes. Likewise, when patients with diffuse skin disease experience skin improvement, new internal organ disease is generally uncommon. The degree of skin thickening varies in extent and progression over time, with some cases stopping after several months with relatively mild disease and others progressing over years to involve most of the body surface (see the Skin Involvement section).

Patients classified in the *limited scleroderma* group may have intermediate involvement of skin extending over the hands and forearms or lower legs but not over the trunk. These patients appear to have an intermediate disease course that is not as severe as that of patients with widespread skin disease. The intermediate group has decreased survival compared with patients who only have sclerodactyly. Although the degree of skin disease provides a rough guide by which to predict disease course, many exceptions have been noted. Variability is associated with other clinically defined factors, including age, gender, and racial/ethnic background. Late age at onset increases the risks for PAH and poor survival. Males may have a more aggressive disease course than do females. African-American or Native-American background predicts a worse disease course and worse multisystem disease.[11,20,21]

## GENERAL PRINCIPLES OF DISEASE EVALUATION

### Measuring Disease Activity and Severity

One of the challenges in studying or caring for patients with scleroderma consists of determining and measuring disease activity, severity, and damage. These measures are not independent of each other and thus cannot be considered in isolation. Activity is a measure of ongoing disease that is dynamic and reversible; it is a direct reflection of ongoing biologic processes such as autoimmune-mediated inflammation or progressive tissue fibrosis. Severity is a measure of the impact of damage on the whole person or a specific organ at any given time. In the extreme, severity is a measure of irreversible end-stage damage. It is important to distinguish reversible disease activity from irreversible damage because although both can cause clinical distress, intervention differs for the two. Patients with scleroderma accumulate irreversible damage over time, and thus the measure of activity is best performed early, when disease has the potential of being reversed.

Measurement of changes in skin thickness (a modified Rodnan skin score) is used as a surrogate measure of disease severity and a predictor of the extent of organ involvement and overall prognosis (see the Skin Involvement section).[37] It is also used as a quantifiable, easily obtainable, and valid score that changes over time in response to therapy. Thus the skin score is now frequently used in clinical trials as a major outcome measure. In patients with diffuse skin disease, improvement in the skin score is associated with a better clinical outcome. A core set of items covering 11 domains (skin, musculoskeletal, cardiac, pulmonary, renal, GI, health-related quality of life measures, global health, RP, digital ulcers, and the biomarkers erythrocyte sedimentation rate and C-reactive protein) is now considered to provide the minimum clinically relevant treatment effect values, as defined by consensus of experts in the field.[38] More detailed scales for specific organs are also in use, as well as other composite measures that include functional testing and clinical outcomes. For example, a skin assessment tool has been developed that combines the modified Rodnan skin score with a visual analogue scale (VAS) score of the patient's assessment of skin activity, a VAS score of the physician's assessment of skin activity, and measures obtained by a durometer.[39] A GI scale is in use to define mild to severe GI disease.[40] Tools to assess severity and outcomes in PAH as related to scleroderma include pulmonary arterial pressures and cardiac function as measured by

right heart catheterization and echocardiography (ECHO), exercise testing as measured by the 6-minute walk and oxygen saturation, New York Heart Association functional class, severity of dyspnea on a VAS, and measures of quality of life and function obtained by the Short Form 36 and the Health Assessment Questionnaire and Disability Index (HAQ-DI) and physician global scale. Other outcome measures that are considered valid include the Raynaud's condition score for severity of Raynaud's phenomenon, forced vital capacity, and Mahler's dyspnea index to monitor ILD, serum creatinine, blood pressure, and complete blood cell count during a scleroderma renal crisis, as well as serum creatine phosphokinase to monitor muscle disease.

A scleroderma severity scale has been developed by Medsger et al.[41] to assess disease severity status in individual patients both at a given time and longitudinally (Table 84-3). This scale is based on scoring that ranges from 0 (normal) to 4 (end-stage) for each organ system involved in scleroderma, including a general measure, along with measures of the peripheral vascular system, skin, joints and tendons, GI tract, lung, heart, and kidney. This severity scale is now used by many experts to define the status of a patient in clinical trials and in research that investigates risk for clinical outcomes.

The HAQ-DI is a self-administered tool initially developed for rheumatoid arthritis to measure functional impairment; it has been validated and used in people with scleroderma as well, in whom it correlates with objective physical signs and reflects the disease course. Higher degrees of impairment are found by HAQ scores in patients with scleroderma who have diffuse skin disease, higher skin scores, abnormal hand function, presence of myopathy or friction rubs, and joint pain.[42] Change in the HAQ score occurs with changes in skin involvement and progressive organ disease.[43] The HAQ is useful in evaluating patients with RP and correlates with the severity and presence of digital ulcers. VAS instruments that assess disease in various domains specific for scleroderma are added to the HAQ to focus on scleroderma-specific issues, including measures of RP and digital ulcers. In addition, the Short Form 36 survey, a simple self-report tool composed of 36 items in 8 domains, is used to assess health-related quality of life.

Developing an activity scale is much more challenging than establishing severity measures. Attempts include evaluating changes in skin score, defining evidence of active lung disease, and documenting congestive heart failure or ongoing scleroderma renal crisis. A composite score generated as a physician global assessment has been used to measure disease activity. This simple global score has some merit, but it is influenced, along with disease activity, by organ severity and irreversible damage.[44] A European study group developed the Valentini disease activity index, which is currently used in clinical studies.[45] This index provides more of an organ-specific assessment than a measure of global activity. The Medsger disease severity scale has the potential to measure disease activity if it is used in studies with serial observations, when individual organ scales can be combined into a composite score. A significant body of

**TABLE 84-3** Medsger Systemic Sclerosis Severity Scale*

| Organ System | 0 (Normal) | 1 (Mild) | 2 (Moderate) | 3 (Severe) | 4 (End Stage) |
|---|---|---|---|---|---|
| General | Wt loss <5%; Hct 37%+; Hb 12.3+ g/dL | Wt loss 5%-10%; Hct 33%-37%; Hb 11.0-12.2 g/dL | Wt loss 10%-15%; Hct 29%-33%; Hb 9.7-10.9 g/dL | Wt loss 15%-20%; Hct 25%-29%; Hb 8.3-9.6 g/dL | Wt loss 20+%; Hct 25%; Hb <8.3 g/dL |
| Peripheral vascular | No RP; RP not requiring vasodilators | RP requiring vasodilators | Digital pitting scars | Digital tip ulcerations | Digital gangrene |
| Skin | TSS 0 | TSS 1-14 | TSS 15-29 | TSS 30-39 | TSS 40+ |
| Joint/tendon | FTP 0-0.9 cm | FTP 1.0-1.9 cm | FTP 2.0-3.9 cm | FTP 4.0-4.9 cm | FTP 5.0+ cm |
| Muscle | Normal proximal muscle strength | Proximal weakness, mild | Proximal weakness, moderate | Proximal weakness, severe | Ambulation aids required |
| Gastrointestinal tract | Normal esophagogram; normal small bowel series | Distal esophageal hypoperistalsis; small bowel series abnormal | Antibiotics required for bacterial overgrowth | Malabsorption syndrome; episodes of pseudo-obstruction | Hyperalimentation required |
| Lung | DLCO 80+%; FVC 80+%; no fibrosis on radiograph; sPAP <35 mm Hg | DLCO 70%-79%; FVC 70%-79%; basilar rales; fibrosis on radiograph; sPAP 35-49 mm Hg | DLCO 50%-69%; FVC 50%-69%; sPAP 50-64 mm Hg | DLCO <50%; FVC <50%; sPAP 65+ mm Hg | Oxygen required |
| Heart | ECG normal; LVEF 50+% | ECG conduction defect; LVEF 45%-49% | ECG arrhythmia; LVEF 40%-44% | ECG arrhythmia requiring therapy; LVEF 30%-40% | CHF; LVEF <30% |
| Kidney | No history of SRC with serum creatinine <1.3 mg/dL | History of SRC with serum creatinine <1.5 mg/dL | History of SRC with serum creatinine 1.5-2.4 mg/dL | History of SRC with serum creatinine 2.5-5.0 mg/dL | History of SRC with serum creatinine >5.0 mg/dL or dialysis required |

*If two items are included for a severity grade, only one is required for the patient to be scored as having disease of that severity level.

CHF, Congestive heart failure; DLCO, diffusing capacity for carbon monoxide, % predicted; ECG, electrocardiogram; FTP, fingertip-to-palm distance in flexion; FVC, forced vital capacity, % predicted; Hb, hemoglobin; Hct, hematocrit; LVEF, left ventricular ejection fraction; RP, Raynaud's phenomenon; sPAP, estimated pulmonary artery pressure by Doppler ECHO; SRC, scleroderma renal crisis; TSS, total skin score; Wt, weight.

research has been devoted to define more precise measures of disease activity and prognosis, including quantification of serologic markers of inflammation, immune activation, and circulating cellular subsets, but none has developed into a widely accepted, clinically useful tool. Currently there is no "gold standard" to measure disease activity in scleroderma, and defining biomarkers or other measures of disease activity remains a major challenge.

## Autoantibodies

Measurement of the autoantibodies present in scleroderma can be helpful in determining the clinical features and prognosis of the disease, in that specific scleroderma-related autoantibodies have been established as strong predictors of disease outcome and the pattern of organ complications (Table 84-4).[46] The three most frequently observed types of scleroderma-specific autoantibodies are anticentromere, antitopoisomerase I, and anti-RNA polymerase III antibodies.

Patients with anticentromere antibodies tend to be older white women. Skin disease usually is limited and most often involves just the fingers. The disease course is indolent, and often the diagnosis is delayed until anticentromere antibodies are discovered or late organ disease becomes evident. Patients frequently have features of the CREST syndrome. Subcutaneous calcinosis is a late manifestation, appearing in areas such as small clusters on the fingers and along the forearm and anterior lower leg. RP can become severe and is associated with increased risk for macrovascular disease. Higher risk for digital gangrene and amputation is noted in the anticentromere-positive group. ILD is less common, but progressive pulmonary vascular disease with PAH and right heart failure occur in a significant proportion of patients. Overall, however, anticentromere antibodies generally are predictors of a favorable prognosis. The presence of anticentromere antibodies can also be seen in patients with primary Sjögren's syndrome who do not have scleroderma.

Antitopoisomerase I antibodies are seen in 30% of African-American patients and are correlated with a poor prognosis and higher scleroderma-related mortality. ILD is highly associated with antitopoisomerase, independent of the degree of skin disease. Patients usually have diffuse skin disease and are at risk for rapid skin changes and renal crisis, usually in the first few years from disease onset. RP may be the first symptom, followed in the first years of disease by skin changes and joint-tendon involvement leading to contractures, particularly in the fingers and elbows. The degree of skin thickening varies a great deal in these patients, but usually the level of severity of skin involvement is established in the first 1 to 3 years of disease.

Anti-RNA polymerase III antibodies are associated with rapid and aggressive diffuse skin disease and renal involvement. These patients have the worst cutaneous involvement, with rapid widespread skin disease associated with signs and symptoms of deep tissue fibrosis involving joints, tendons, and muscles. Flexion contractures of the fingers, wrist, elbows, shoulders, hips, knees, and ankles are complications that can occur within a few months of onset of disease activity. Friction rubs are common. A "fibrosing" myopathy without inflammation, along with skin and joint disease, leads to loss of strength and flexibility. Significant disability occurs in early stage disease. Anti-RNA polymerase III–positive patients are relatively protected from the development of ILD or pulmonary vascular disease and are not likely to have severe GI disease, although a small study has shown an association with gastric antral vascular ectasia.[47] Approximately 25% to 40% of patents have a high risk for developing scleroderma renal disease with hypertensive crisis in subjects positive for this autoantibody. Risk is greatest in the early years, when skin is rapidly changing. Heart disease can be a late complication, but major disability from skin and deep tissue disease is the most worrisome long-term problem in this subtype of scleroderma. Studies conducted in different countries have consistently found an association between scleroderma and underlying malignancy in subjects positive for anti-RNA polymerase III.[48-50] The detection of cancer and the onset of scleroderma have been described in close temporal relationship, indicating the importance of appropriate screening for underlying neoplastic disease in this subset of patients.

Other antinucleolar antibodies are found among subgroups of patients with scleroderma and are associated with specific clinical phenotypes and clinical outcomes. Of these, anti-Th/To antibodies and anti-PM/Scl antibodies are associated with limited skin disease, whereas anti-U3-RNP (fibrillarin) antibodies are associated with diffuse disease. Patients with anti-Th/To antibodies are at increased risk for development of severe ILD and pulmonary hypertension. Anti-U3-RNP is another predictor of a less favorable prognosis with a higher frequency of internal organ involvement, including ILD, PAH, and renal crisis. It is frequently present in African-Americans and is associated with diffuse

**TABLE 84-4** Autoantibodies and Associated Phenotypes in Scleroderma

| Antigen | Subtype | Clinical Phenotype |
|---|---|---|
| Topoisomerase 1 (Scl-70) | Diffuse | Pulmonary fibrosis, cardiac involvement |
| Centromere (protein B, C) | Limited | Severe digital ischemia, PAH, sicca syndrome, calcinosis |
| RNA polymerase III | Diffuse | Severe skin disease, tendon rubs, cancer, GAVE, renal crisis (±sine scleroderma) |
| U3-RNP (fibrillarin) | Diffuse or limited | Primary PAH; esophageal, cardiac, and renal involvement; muscular disease |
| Th/To | Limited | Pulmonary fibrosis, rare renal crisis, lower GI dysfunction |
| B23 | Diffuse or limited | PAH, lung disease |
| Cardiolipin, $\beta_2$GPI | Limited | PAH, digital loss |
| PM/Scl | Overlap | Myositis, pulmonary fibrosis, acro-osteolysis |
| U1-RNP | Overlap | SLE, inflammatory arthritis, pulmonary fibrosis |

GAVE, Gastric antral vascular ectasia; GI, gastrointestinal; GPI, glycoprotein I; PAH, pulmonary arterial hypertension; RNP, ribonucleoprotein particle; SLE, systemic lupus erythematosus.

Modified from Boin F, Rosen A: Autoimmunity in systemic sclerosis: current concepts. *Curr Rheumatol Rep* 9:165–172, 2007.

skin disease and poor prognosis. Hyperpigmented and hypopigmented skin changes are common, and contractures of large joints associated with inflammatory or fibrotic muscle disease lead to significant morbidity. Cardiac disease is often subclinical until late-stage disease, when both right and left heart failure can occur.

Anti-PM/Scl, anti-Ku, and anti-U1-RNP antibodies are seen mainly in patients with overlap syndromes. The presence of anti-Pm/Scl is associated with acute onset of weakness as a result of inflammatory muscle disease and a higher risk for ILD. Anti-Ku positivity is strongly associated with muscle and joint involvement. Anti-U1-RNP is seen in patients with mixed connective tissue disease and is common among African-Americans with limited scleroderma. Polyarthritis, myositis, and lupus with skin or renal involvement are common complications. A subset can experience diffuse skin disease, and risk for late onset of PAH is increased overall. Although uncommon, anti-B23 autoantibody is associated with PAH. Up to 11% of patients with scleroderma can test negative for anti-nuclear antibodies (ANAs).

## CLINICAL MANIFESTATIONS

### General Principles

Several basic principles can be of help in managing patients with scleroderma. The first principle is that scleroderma encompasses subsets of disease, each with a unique clinical phenotype; thus carefully determining the specific subtype of the patient sets the scene for deciding the most appropriate therapeutic approach. Clinical problems and disease activity in scleroderma are highly variable in expression, even within a given subtype. This variability is thought to be a result of different susceptibility to, or risk for, systemic complications. It is also due to the presence of a dynamic biologic process unique to scleroderma. Therefore, patients move through stages of the disease process with levels of disease activity that vary with time and with a possible shift in nature. Signs of classic inflammatory events are often present during the initial phase of the disease, but later, an indolent subclinical fibrotic process is dominant and gradually causes organ damage.

Although the skin may be the site of the most dramatic physical findings, scleroderma is a multisystem disease, and the physician must search for early organ-based complications, including cardiopulmonary, GI, renal, or musculoskeletal involvement. Understanding the shortcomings of current investigations, not getting locked into "traditional" therapy, focusing on an organ-specific approach, and defining the disease subtype and level of disease activity are most important in establishing optimal management. Although no good-quality studies have been conducted to prove the effectiveness of this approach, it seems reasonable to use combination therapy with rapid control of the inflammatory immune process early on, followed by maintenance immunosuppression for an extended time. The antiinflammatory program is then coupled with organ-specific therapy (see later sections). The missing component in this comprehensive approach is the availability of a direct antifibrotic agent able to prevent the progression of fibrosis once the inflammatory phase is under control. Obviously, early intervention is most important for success; once irreversible tissue or organ damage is noted, supportive care becomes the main and often the only option. More recently, myelo- or immune-ablative therapeutic protocols with or without autologous hematopoietic stem-cell transplantation have shown the ability to achieve rapid control of skin disease and stabilization of lung function.[51-53] However, long-term data are not yet available to define how lasting these effects are, and the treatment mortality associated with these approaches remains significant.

### Raynaud's Phenomenon

**KEY POINTS**

- **RP is common in the general population and usually presents with a benign clinical course.**
- **In scleroderma, RP is more clinically symptomatic and can be associated with manifestations of digital ischemia.**
- **Abnormal vasomotor regulation and progressive endothelial and structural vessel disease occur in RP associated with scleroderma.**
- **Treatment for RP must include control of excessive vasoreactivity, modification of structural vascular disease, and prevention of microthrombotic events.**

RP is an exaggerated vascular response of the digital arterial circulation triggered by cold ambient temperature and emotional stress. The diagnosis of RP is based on a history of excessive cold sensitivity and recurrent events of sharply demarcated pallor and/or cyanosis of the skin of the digits (Figure 84-2). Blanching reflects digital arterial vasospasm, and cyanosis occurs as a result of the deoxygenation of sluggish venous blood flow. Some skin blushing (redness) may follow as a result of reactive hyperemia after regular blood flow has been restored. RP occurs in 3% to 15% of the general population. It is more common among females (3 to 4:1) and is likely to begin before age 20 years. During cold exposure (particularly during shifting temperatures and winter months), RP attacks increase in frequency and

**Figure 84-2** Active Raynaud's phenomenon with well-demarcated pallor at the fingertips in a patient with scleroderma.

intensity. RP can be categorized clinically into primary and secondary forms (Figure 84-3). Primary RP occurs when no disease process is associated with recurrent vasospastic events. Distinguishing primary RP from that associated with an underlying disorder is frequently challenging. Young age at onset (<20 years), symmetric manifestations of symptoms, mild to moderate severity, no association with digital ulceration or tissue gangrene, normal nail-fold capillary examination, and a negative ANA titer are all indicative of primary RP.[54] Secondary RP occurs in a variety of settings, including connective tissues disorders and other rheumatic conditions, occupational trauma (e.g., hypothenar hammer syndrome), the use of certain drugs (e.g., antimigraine agents, ergotamine derivatives, and bleomycin), increased blood viscosity, and compressive or obstructive vascular disease (e.g., thoracic outlet syndrome, atherosclerosis, and thromboangiitis obliterans).

Nail-fold capillaroscopy is the tool most commonly used at the bedside to distinguish patients with primary RP from those with scleroderma or another rheumatic disease. Maricq and LeRoy[55] first described the abnormal pattern of nail-fold capillary vessels seen in scleroderma. Sulli and colleagues[56] provided further evidence regarding the utility of assessing patterns of nail-fold capillary abnormalities to monitor progression toward more severe disease manifestations. The simplest method of detection is to coat the skin

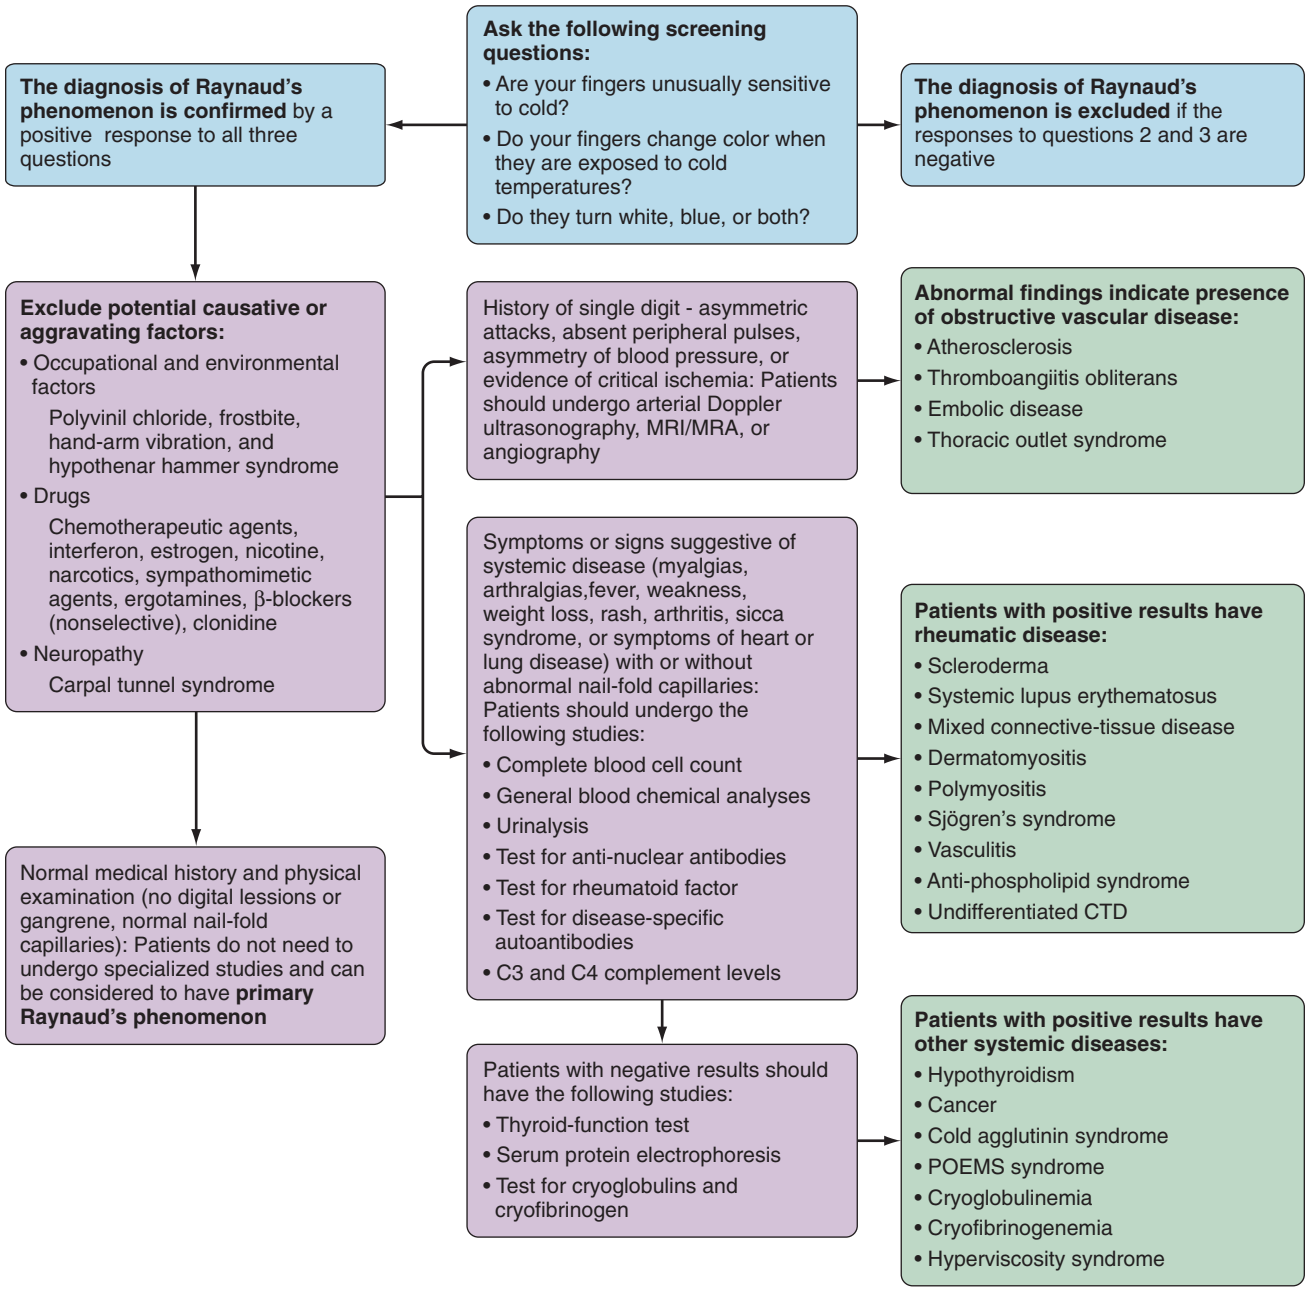

**Figure 84-3** Approach to diagnosis of Raynaud's phenomenon. CTD, Connective tissue disease; MRA, magnetic resonance angiography; POEMS, polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes.

of the nail fold with immersion oil and then view the area using a bifocal dissecting microscope or a handheld device such as an ophthalmoscope set at 20 or 40 diopters. Portable dermatoscopes can also be used to perform a rapid and effective examination of the nail-fold area.[57] A computerized nail-fold videocapillaroscopy technique is used in specialty centers. This technique provides enhanced digital images that can assess local blood flow and follow the disease course.[58] Although patients with primary RP may have normal, thin, palisading nail-fold capillary loops (Figure 84-4), in secondary RP, capillary loop dilation/enlargements and dropouts represent the salient features. Patterns of capillary abnormalities appear to correlate with the course of systemic disease manifestations. Capillary dilation (giant capillaries), microhemorrhages, and some disorganization of the capillary network are typical of early disease; dropouts, avascular areas, and signs of neoangiogenesis with bizarre architectural distortion manifest at later stages of scleroderma.[59,60] Clinical features of scleroderma will develop in approximately 20% to 30% of patients with RP and abnormal nail-fold capillary changes, usually within a 2- to 3-year period.[34] Patients presenting with RP, nail-fold capillary changes, and the presence of a scleroderma-related autoantibody have a 70% to 80% chance of developing scleroderma within 2 to 3 years from presentation. Therefore, capillaroscopy represents an important standard tool that can be used to examine patients presenting with RP.

In scleroderma, RP and digital ischemia are the clinical manifestations of both fixed structural vascular disease and abnormal regulation of local vasomotor control. Cold-induced vasoconstriction of peripheral blood vessels normally occurs via sympathetic stimulation. Abnormal thermoregulation is associated with a nonvasculitic vasculopathy characterized by endothelial dysfunction and a fibrotic proliferation, which produces an increase in collagen content of the intima of small and medium vessels and causes loss of vessel flexibility and obliteration of their lumina. Digital pitting with loss of fingertip tissue and small, painful, superficial ulcerations are very common and usually are noted as a consequence of disease affecting the small arteries and arterioles of the skin (Figure 84-5). Large, deep ulceration of the distal portion of the finger is a consequence of larger vessel (e.g., digital artery) occlusion associated with severe vasospasm. The latter event usually presents as a sharp demarcation of the distal digit with intense, localized pain resulting from ischemia. Failure to reverse these events may lead to loss of the entire digit or limb as a result of deep tissue infarction.

Although a number of methods may be used to objectively score attacks of RP, no test is considered practical or reproducible enough to replace the clinical criteria for diagnosis and management. Patients with an active RP attack will present with coolness of the involved distal fingertips and/or toes, which can be associated with a line of demarcation of skin pallor or cyanosis. In later stages of severe RP, if the condition is not treated, one may find signs of critical digital ischemia resulting in painful and unremitting digital ulcerations. Such findings warrant immediate medical

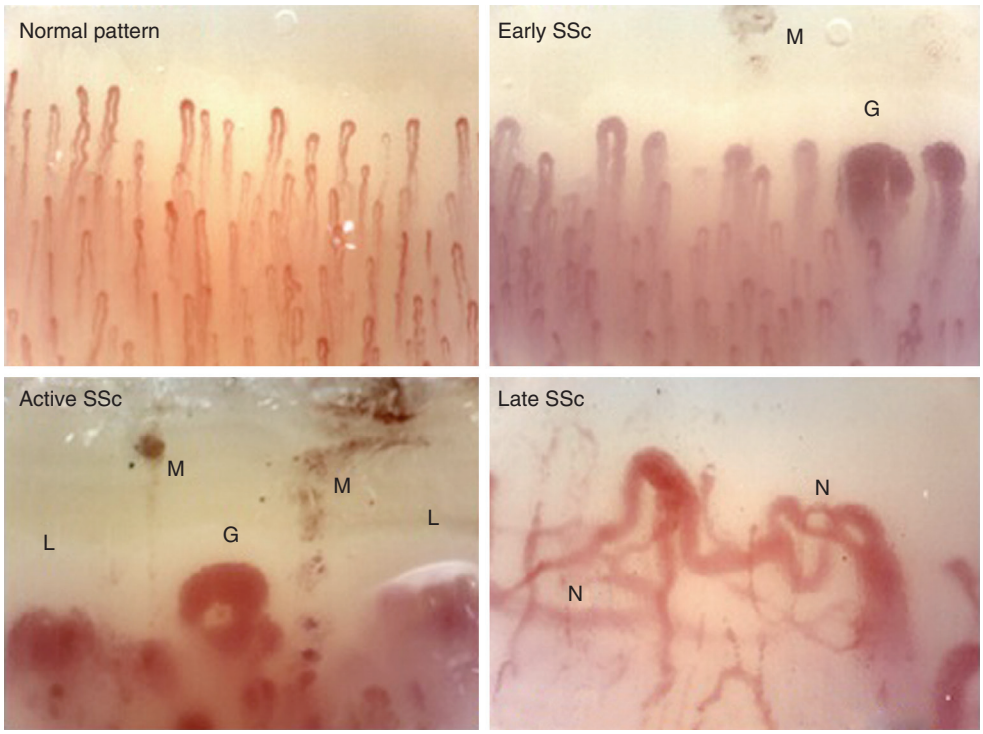

**Figure 84-4** Patterns of nail-fold capillary abnormalities assessed by video capillaroscopy in patients with scleroderma. *Top right,* "Early pattern" shows the presence of few enlarged/giant capillaries, few capillary hemorrhages, and no evident loss or distortion of capillaries. *Bottom left,* "Active pattern" presents with frequent dilated capillary loops, frequent microhemorrhages, moderate loss of capillaries, and mild disorganization of the capillary architecture. *Bottom right,* "Late pattern" is characterized by severe loss of capillaries with avascular areas, ramified/bushy capillaries (neovascularization), and disorganization of the normal capillary architecture. **Figure 84-5** Scleroderma and Raynaud's phenomenon can be associated with digital ulcerations and severe digital ischemia. **A**, Traumatic ulcers over the proximal interphalangeal joints. **B** and **C**, Ischemic digital ulcerations as a result of small arterial disease. **D**, Digital gangrene as a result of macrovascular disease.

treatment. Several methods may be used to assess the severity of RP. Traditionally, the patient is asked to use a diary to record the frequency and duration of attacks during days of usual activity. Raynaud's condition score is a patient-based measure that takes into account the impact of RP on the patient, including pain, discomfort, and effect on daily function. Other laboratory-based measures, including laser Doppler, thermography, and plethysmography methods, are used in an attempt to obtain objective data.

## Treatment of Raynaud's Phenomenon and Digital Ischemia

The primary goal in the management of RP is prevention of digital ischemia through the use of nonpharmacologic and pharmacologic measures (Figure 84-6). In the setting of acute digital ischemia, rapid intervention using both treatment modalities is required. The primary and most important nonpharmacologic therapy for prevention is avoidance of cold ambient temperatures, particularly transitioning from a warm or hot environment to a cold one. A warm ambient temperature reduces the frequency and severity of RP. All patients with RP should understand that clothing should be layered and loose-fitting, with the goal of maintaining a warm core body temperature, not just warmth of the affected extremities. Patients who have an acute ischemic event are best treated with rest in a warm environment (at home or in the hospital), insulated from cold temperatures. Other potential therapies include minimizing emotional distress (reducing sympathetic tone) and avoiding aggravating factors such as smoking, sympathomimetic drugs (e.g., preparations for the common cold), migraine headache medications (e.g., serotonin agonists), and nonselective β-blockers (e.g., propranolol). Although behavioral therapies (including biofeedback, autogenic training, and classical conditioning) are reported to be helpful, their benefit is controversial, and they play no role in the management of acute ischemia related to scleroderma.[61] In fact, biofeedback alone is not helpful for primary RP.

Drug therapy for RP in scleroderma includes the use of a variety of oral or systemic vasodilators. Calcium channel blockers are considered to be first-line therapeutic agents in the treatment of RP. This class of medication works primarily by inducing arterial vasodilation through direct inhibition of contraction of vessel smooth muscle cells; however, these agents provide additional benefits by reducing oxidative stress and inhibiting platelet activation.[62,63] Most published studies evaluating the efficacy of calcium channel

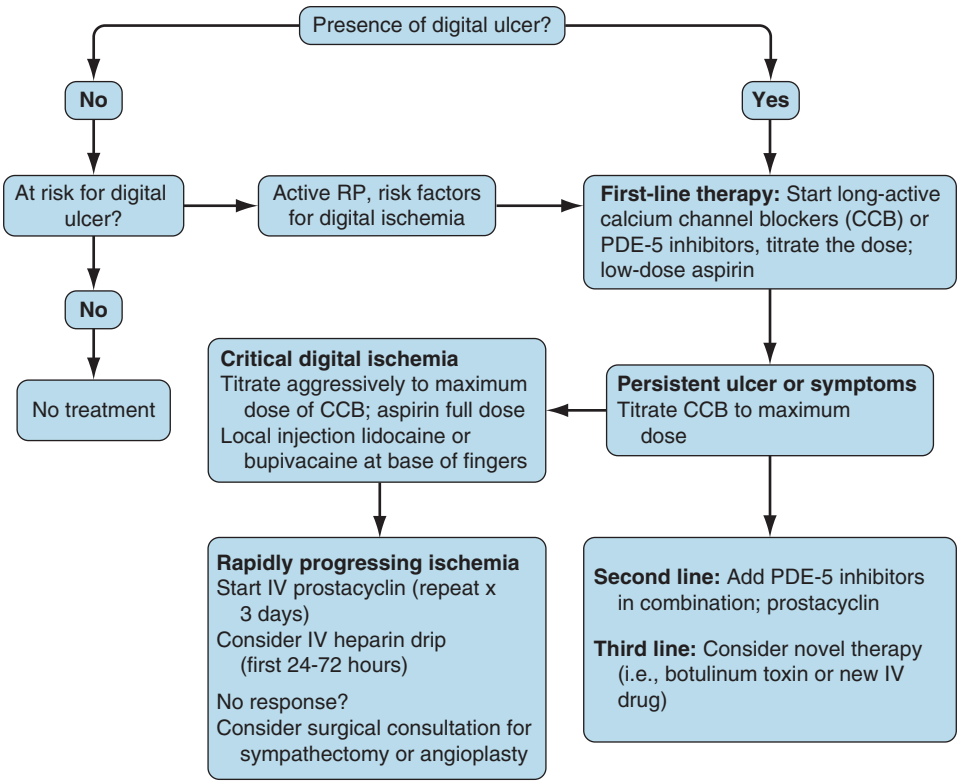

**Figure 84-6** Approach to drug treatment of Raynaud's phenomenon (RP) and acute digital ischemia. CCB, Calcium channel blockers; IV, intravenous; PDE-5, phosphodiesterase-5; SSRI, selective serotonin reuptake inhibitor.

blockers in RP have used dihydropyridines (e.g., nifedipine, amlodipine, nisoldipine, isradipine, and felodipine), and few have looked at nondihydropyridines. The calcium channel blockers appear to be more efficacious in primary than in secondary RP.[64,65] A meta-analysis of 17 studies evaluating the efficacy of short- and long-acting formulations of calcium channel blockers reported a 33% reduction in attack severity and a near 50% reduction in the number of attacks per week.[66] The current recommendation is to use an extended-release formulation of a calcium channel blocker for treatment of nonurgent RP. The dose should be titrated to clinical efficacy, but common adverse effects (e.g., hypotension, headache, and pedal edema) should be monitored. For urgent cases of RP, a short-acting formulation of the medication is preferred, but titration should be carefully monitored. Although calcium channel blockers are the agents most likely to be effective, a host of other vasodilators are used, including nitrates, phosphodiesterase-5 inhibitors (e.g., sildenafil), intravenous (IV) prostaglandins, and sympatholytic agents (e.g., prazosin).

Among other agents being tested in the treatment of RP are drugs that enhance nitric oxide availability—serotonin uptake blockers (e.g., fluoxetine), Rho-kinase inhibitors, local injection of botulinum toxin (Botox), antioxidants (acetylcysteine), angiotensin receptor blockers, and selective $\alpha$2-adrenergic receptor antagonists. A combination of these agents, if tolerated, can be used in refractory cases. Various formulations of topical and oral nitroglycerin are used.[67,68] Although some degree of efficacy is obtained, use of nitroglycerin is limited by substantial adverse effects, including headache, dizziness, and local skin irritation. The cyclic guanine monophosphate phosphodiesterase-5 inhibitors are thought to be effective in the treatment of RP by sustaining the vasodilatory effect of nitric oxide.[69,70] Studies using phosphodiesterase inhibitors have reported variable effects, and the ideal drug and dosing have not yet been defined. Despite the theoretical advantage of ACE inhibitors, a study of quinapril showed that these medications did not affect the occurrence of digital ulcers or the frequency or severity of RP episodes.[71] Thus, although ACEs are critical for the treatment of a scleroderma renal crisis (see the Renal Involvement section), they do not have a major role in the management of RP.

New emphasis is being placed on the prevention of scleroderma vascular disease through the use of immunosuppressive and vasoprotective drugs. HMG-CoA (3-hydroxy-3-methylglutaryl-coenzyme A) reductase inhibitors (statins) can modify progression of vascular injury and prevent vascular ischemia through different pleiotropic functions, such as by improvement of endothelial dysfunction, reduction of clotting, and introduction of some antiinflammatory effects.[72,73] Data suggest that statins may increase the number of endothelial progenitor cells and improve vascular remodeling after injury.[74,75] In a randomized, placebo-controlled study of patients with scleroderma who had secondary RP, statin use significantly decreased the number of digital ulcers that formed.[76]

IV infusions of vasodilating prostaglandins (e.g., alprostadil, epoprostenol, iloprost, and treprostinil) reduce the severity and frequency of RP attacks and are most

helpful during periods of sustained critical ischemia. These prostaglandins are efficacious in the treatment of RP because of their strong vasodilating effect, inhibition of platelet aggregation, and enhancement of vascular function through other mechanisms. IV prostacyclins can be given intermittently to patients with scleroderma during winter months or throughout the year, or they can be used acutely during a vascular crisis. Oral prostaglandins have variable absorption and are not yet available.

Endothelin-1 is strongly implicated in the pathogenesis of RP and the vascular disease of scleroderma.[77] In a randomized, placebo-controlled, double-blind multicenter study, bosentan, an endothelin-1 receptor blocker, showed efficacy in preventing new digital ulcers, along with improved hand function, but it did not improve healing of existing ulcers compared with placebo.[78]

Sympathectomy is a viable option for patients with RP who do not respond to medical therapy and should be considered as an acute intervention during a critical ischemic event. Localized digital sympathectomy with lysis of fibrosis around the vessel is effective for acute ischemia and for the most part has replaced cervical sympathectomy.[79,80] Responses to sympathectomy are not sustained over time, suggesting limited long-term benefit. In fact, RP attacks eventually recur, and medical therapy is needed to prevent new events. Injections of botulinum toxin A to the hands and fingers have shown favorable effects both in managing acute digital ischemia and in controlling chronic vasospastic activity.[81] Large, randomized, controlled trials are not yet available to confirm the validity of initial reports.

Careful assessment for correctable macrovascular disease should be performed when acute digital ischemia occurs, particularly when the entire finger is demarcated or when the event involves a lower extremity. In this setting, appropriate studies such as arterial Doppler ultrasound or angiographic imaging are warranted. If macrovascular disease is present, vascular surgery may help alleviate the occlusive process. Preferential involvement of the ulnar artery has been reported in patients with scleroderma.[82]

Patients with critical digital ischemia should be hospitalized to reduce vasospastic activity, maintain warmth, and permit rapid initiation of vasodilator therapy. IV vasodilating prostaglandins can be infused to maximize vasodilation. Anti-platelet therapy with low-dose aspirin may be useful, but its benefit is unproven in the acute setting. Heparinization may be considered during acute ischemic crises of the digits, but chronic anticoagulation in scleroderma is not recommended. Fibrinolysis to manage acute occlusion of larger arterial vessels can be considered, but this practice has not been studied for routine use in scleroderma-related critical digital ischemia. Chemical sympathectomy of the affected digit, performed by local infiltration with lidocaine or bupivacaine, may provide immediate relief. For refractory cases, a surgical approach to digital sympathectomy is used.

Ischemic digital lesions should be treated with topical antibiotics and daily cleansing with soap and water. Débridement procedures should be performed very cautiously because tissue trauma may extend the injury as a result of the avascular nature of the digital tissue. Digital lesions that progress to dry gangrene should be permitted to undergo autoamputation. Surgical amputation is best offered only in cases of intractable pain or deep tissue infection.

## Skin Involvement

The most overt clinical manifestation of scleroderma is skin disease. The degree of involvement can vary among patients, and involvement can change in severity and distribution over time in the same individual. Almost every patient with scleroderma presents with skin thickening and hardening due to increased collagen and extra-cellular matrix deposition in the dermis. The distribution of skin changes is characteristic, with more frequent and intense involvement of fingers, hands, forearms, distal legs, feet, and the face, as well as, to a lesser degree, the proximal limbs and anterior trunk. Sparing of the midback is typical. Scleroderma is classically subdivided into *limited* and *diffuse* cutaneous forms (Figure 84-7). Limited scleroderma is defined by skin thickening that is restricted to the face and limbs distal to the elbows and knees. Commonly, in this form of the disease, only the fingers and the face are involved. In contrast, diffuse cutaneous involvement is characterized by widespread skin thickening, including proximal limbs and truncal areas. Proximal skin involvement defines the diffuse cutaneous subset but may be absent in early stages of disease when signs of skin thickening are not prominent, other disease manifestations (e.g., RP and nail-fold capillary abnormalities) are more apparent, and evidence of internal organ involvement is still lacking.

Traditionally, patients are clustered into limited and diffuse skin subsets, but evidence suggests the existence of an intermediate group of patients. Each subset of disease defined by the degree of skin thickening has a unique pattern of disease manifestation and risk for specific clinical outcomes. Therefore, expression of skin disease can be used as a predictor or a "clinical biomarker" of the disease course. The variable degree of skin involvement can be quantified by physical examination. The most widely accepted scoring system (the modified Rodnan skin score) is applied by pinching the skin in 17 different body areas and subjectively averaging the thickness of each specific site from 0 (normal) to 3 (very thick; Figure 84-8). The skin score (maximum, 51) is a useful clinical measurement tool that can be used to quantify the severity of skin disease.[37] Although the overall extent of skin involvement as measured by the skin score can predict certain clinical outcomes, it does not define the quality of the skin process nor the level of disease activity at any single point in time. Therefore, it is important to follow up on the skin score over time and measure changes sequentially to monitor disease progression.

Cutaneous involvement in scleroderma begins with clinical signs of inflammation, which is called the *edematous phase* because it is characterized by nonpitting edema of affected body areas. In patients with limited scleroderma, this event is mild and is restricted to the digits; however, in the diffuse form of the disease, cutaneous swelling and edema can be widespread and so impressive in the limbs that it mimics a fluid overload state such as congestive heart failure. Edema can also cause local tissue compression. For example, upon involvement of the wrist area, patients with scleroderma are not infrequently diagnosed with carpal tunnel syndrome (especially at disease onset) to explain hand and wrist discomfort. In association with edema, signs and symptoms of inflammation are common. Erythema of the skin and intense pruritus and pain (see Figure 84-7C)

**Figure 84-7** Skin involvement in scleroderma is subdivided into "limited" and "diffuse" cutaneous forms. **A**, Sclerodactyly in limited cutaneous disease. **B**, Truncal changes in diffuse cutaneous disease. **C**, Inflammatory signs in early active skin disease. **D**, Finger contracture in the chronic fibrotic phase of skin involvement in scleroderma.

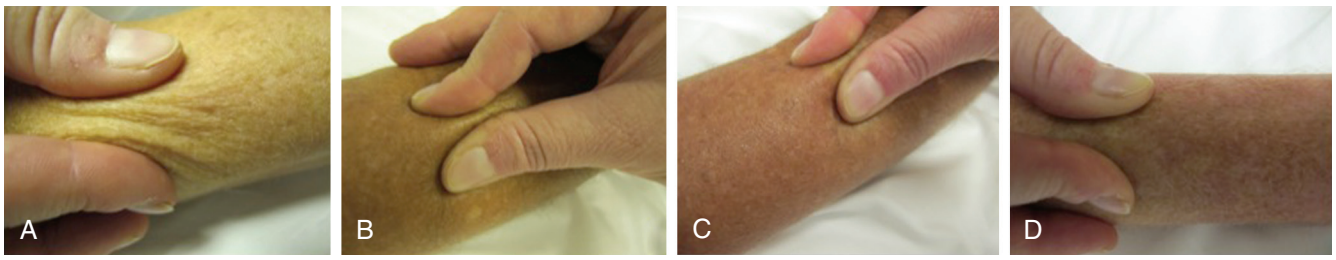

**Figure 84-8** Method used to semi-quantify skin thickness in scleroderma. The modified Rodnan skin score is obtained by clinical palpation of 17 different body areas (fingers, hands, forearms, upper arms, chest, abdomen, thighs, lower legs, and feet) and subjective averaging of the thickness of each specific site: **A,** 0 = normal; **B,** 1 = mild; **C,** 2 = moderate; and **D,** 3 = severe. The maximum score is 51.

are characteristic of advancing active diffuse skin disease. This pain has a neuropathic quality with a reported "pins and needles" sensation. The disease process leads to loss of skin appendages, as well as decreased hair growth and loss of sweat and exocrine glands; thus the skin surface becomes dry and uncomfortable. Small papules can be seen in areas of trauma as the result of scratching, giving the surface a cobblestone texture. The edematous phase continues for several weeks but eventually gives way to a fibrotic stage, with protracted activity that may last months or years.

During the fibrotic phase, acute inflammation is clinically less obvious, and deposition in the dermis of excessive collagen and other extra-cellular material thickens the skin, making it inflexible and causing further loss of skin appendages. Fibrosis extends beyond the dermis into the deeper layers with loss of subcutaneous adipose tissue

(lipodystrophy). In late stages of the disease, skin actually thins with atrophy and has a non-inflammatory bound-down appearance. Deeper tissue fibrosis causes permanent contractures around joints or may involve underlying muscle, causing a myopathy (see Figure 84-7D). Patients with diffuse cutaneous scleroderma experience the most dramatic widespread skin changes; those with limited skin disease may note only puffy fingers and digital thickening typical of sclerodactyly. A masked facies, small oral and orbital apertures, and vertical furrowing of the perioral skin are consequences of skin and soft tissue fibrosis. In some patients, gum atrophy and facial skin tightening make the front teeth appear more prominent. Flexion contractures of fingers, wrists, and elbows often appear as a result of dermal sclerosis and fibrosis with atrophy of underlying tissues. Skin ulcers can develop as a complication of avascular fibrotic or damaged thinned skin and are very common at sites of trauma, such as over the digital MCP or proximal interphalangeal (PIP) joints or at the tip of the elbows, particularly when joint contractures are present at these sites (see Figure 84-5A). Ulcerations may be noted as a result of underlying vascular disease and tissue ischemia (see Treatment of Vascular Disease section). Ankle or lower extremity ulcers occur rarely as a result of macrovascular occlusive disease or comorbid conditions (venous disease). Areas of hypopigmentation (vitiligo-like) and/or patches of depigmentation with preserved perifollicular pigmentation (a "salt-and-pepper" appearance) can develop, typically on the face, arms, and trunk (Figure 84-9A). General tanning of the skin may be seen, even in the absence of sun exposure.

Active skin involvement might persist for the first 12 to 18 months of the disease, with no further clinical signs of inflammation or progressive skin fibrosis seen after this interval. During this later stage, the skin begins to repair and can return to normal texture or, in areas most severely affected (e.g., the fingers and hands), it can become thin and atrophic. During this recovery phase, new robust hair growth is seen, particularly on the forearms, and itching and pain disappear, consistent with spontaneous resolution of disease activity. After years from disease onset, the skin rarely relapses again into an active phase and gradually can recover normal texture and color. Patients who, over time, experience the establishment of a phenotype that is limited to the fingers (plus or minus facial changes) do not undergo conversion to the diffuse form of the disease.

Telangiectasias are erythematous matted skin lesions of vascular origin; for this reason, they blanch upon application of local pressure. Telangiectasias are composed of vasodilated postcapillary venules without evidence of inflammation and resemble the type of lesions seen in Osler-Weber-Rendu disease (hereditary hemorrhagic telangiectasia). Telangiectasias develop primarily on the fingers, hands, face, and mucous membranes, but they also may be found on the limbs and trunk (Figure 84-9B). They tend to become more numerous over time in both limited and diffuse types of skin disease and are more obvious in white patients with limited scleroderma. The biologic mechanism leading to the development of telangiectasias in scleroderma is thought to be related to the underlying chronic tissue hypoxia that stimulates abnormal secretion of vascular growth factors (e.g., vascular endothelial growth factor). Thus the development of telangiectasias may indicate ongoing vascular injury and abnormal vascular repair or angiogenesis. The total burden of telangiectasias is associated with increased risk of pulmonary hypertension, suggesting that they are clinical biomarkers of systemic vascular disease. Nail-fold capillary abnormalities can be observed after immersion oil is applied to the skin surface at the base of the fingernails, and direct visualization is performed using an ophthalmoscope or by videocapillaroscopy. In early scleroderma, dilated capillary loops (giant capillaries) and microhemorrhages may be seen. At later stages, the nail-fold capillaries are attenuated and disorganized (see Figure 84-4).

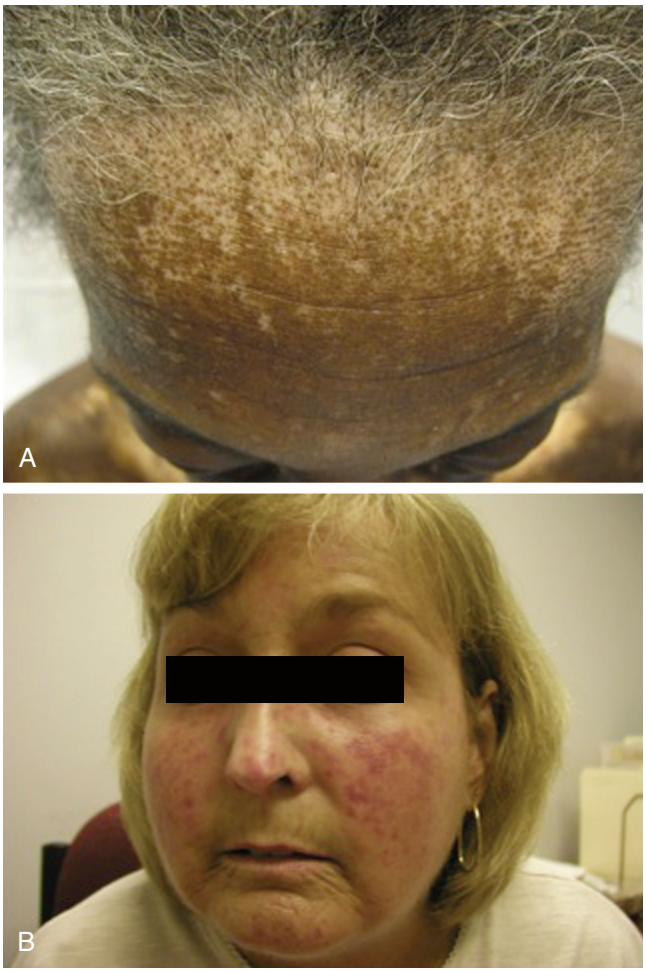

**Figure 84-9** Skin manifestations in patients with scleroderma. **A**, Depigmentation with preserved perifollicular pigmentation ("salt-and-pepper") appearance of the forehead. **B**, Large facial telangiectasias.

Despite evidence of active inflammation during the early edematous phase of scleroderma skin involvement, administration of systemic corticosteroids has not uniformly shown efficacy in stopping disease progression. A variety of other immunomodulatory drugs and newer agents with potential "disease-modifying properties" (i.e., antifibrotic properties) have been used to control the skin disease, but to date, none has proved uniformly successful. In the early active stage of diffuse scleroderma, pruritus can be one of the most distressing symptoms. Antihistamines, analgesics, or tricyclic anti-depressants (e.g., doxepin) are often used but usually provide only partial benefit. Dryness of the skin surface results from damage to the exocrine structures caused

by decreased or absent natural oil (sebum) production. This dryness can worsen pruritus, leading to skin trauma as a result of repetitive scratching. Ulceration and secondary tissue infection also may result. The best approach to treatment is characterized by frequent topical application of an emollient preparation, periodic cleansing with soap and water, and use of topical antibiotics for any traumatic skin ulceration. Physical therapy is important to prevent severe skin and joint contractures and to help patients with activities of daily living.

## Gastrointestinal Involvement

**KEY POINTS**

- **Manifestations of gut dysmotility are universally present in patients with scleroderma and can affect any segment of the GI tract.**
- **Involvement of the upper GI tract is more common than the lower GI tract and can present with severe symptoms.**
- **Dysfunction and failure of the lower GI tract are associated with poor prognosis.**

Almost every patient with scleroderma has symptoms of GI disease, ranging from mild gastroesophageal reflux disease (GERD) to severe bowel dysfunction, which can be life threatening. Virtually any segment of the GI tract can be affected (Table 84-5).

**TABLE 84-5** Gastrointestinal Manifestations of Scleroderma

| Site | Manifestation | Management |
|---|---|---|
| Oropharynx | Perioral tight skin<br>Decreased oral aperture<br>Periodontitis, gum disease<br>Dry mouth<br>Swallowing difficulties<br>Coughing, aspiration | Regular dental and periodontal care<br><br>Artificial saliva<br>Targeted swallowing exercises and rehabilitation |
| Esophagus | Acid reflux (heartburn)<br>Dysphagia<br><br>Strictures<br>Barrett's esophagus | Lifestyle modifications<br>Proton pump inhibitors<br>Prokinetics<br>Endoscopic treatments and procedures |
| Stomach | Gastroparesis, dyspepsia<br>Gastric antral vascular ectasia | Prokinetics<br>Proton pump inhibitors, iron replacement<br>Endoscopic laser or cryotherapy<br>Transfusions<br>Surgery |
| Small and large intestine | Hypomotility, constipation<br><br>Bacterial overgrowth, diarrhea<br>Pseudo-obstruction<br>Pneumatosis intestinalis<br>Malabsorption<br>Colonic pseudodiverticula | Mild laxatives<br>Promotility agents<br>Rotational antibiotics<br>Octreotide<br>Avoidance of surgery<br>Enteral or parenteral nutrition support |
| Anorectum | Sphincter incompetence | Biofeedback, sacral nerve stimulation, surgery |

### Oropharynx

Patients may report that chewing is difficult because of decreased facial flexibility caused by skin and deeper tissue fibrosis. Perioral skin tightening can result in a decreased oral aperture and the inability to open the mouth wide enough for proper dental care or to bite into large solid foods such as an apple (Figure 84-10). Dry membranes resulting from decreased saliva production can lead to difficult mastication. In some patients, periodontal disease and gum regression cause loosening of teeth, which further affects chewing capacity.

Upper pharyngeal function is usually normal, but in a subset of patients a myopathy may develop that causes weakness of pharyngeal muscles, mimicking a neuromuscular disease.[83] This manifestation is characterized by pharyngeal dysfunction with problems initiating swallowing and frequent coughing as a result of laryngeal penetration, and it can be associated with increased risk for aspiration of foods or liquids. Although few pathologic studies of the upper pharyngeal structures have examined scleroderma, both myositis and fibrosis are known to occur.

### Esophagus

Dysphagia resulting from esophageal disease is the most common GI symptom, occurring in approximately 90% of patients. Heartburn, regurgitation, and dysphagia for pills and solids (more than for liquids) are the most common symptoms, but atypical retrosternal pain (particularly at night), periodic cough, a sense of food "sticking" in the esophagus, and nausea can result from esophageal dysfunction. Esophageal involvement in scleroderma is characterized by loss of normal smooth muscle function, especially in the lower two-thirds of the esophagus, and hypotonia of the lower esophageal sphincter (Figure 84-11A). Functional studies of esophageal motility suggest that neural dysfunction is common in patients with scleroderma and that it may precede myopathic dysfunction and histologic changes in smooth muscle layers.[84] Manometric evaluation has identified the presence of esophageal hypomotility in areas that later did not show any histologic abnormality of the smooth muscle. Other studies have shown esophageal smooth muscle activity in response to pharmacologic stimulation (methacholine challenge) early in the disease, but not in patients with more advanced scleroderma. The cause of these abnormalities is unknown, but clear evidence indicates that neural dysfunction precedes muscle disease.

Tissue fibrosis is often evoked as the cause of esophageal disease in scleroderma. However, pathologic studies demonstrate atrophy of the smooth muscle layers of the distal esophagus in the absence of significant fibrosis. Ischemia of the esophagus in scleroderma is suggested by functional studies that show impaired esophageal blood flow after exposure to cold temperatures and institution of rewarming protocols. Non-inflammatory intimal layer hyperplasia in the arterioles of the GI tract has been described. Inflammatory infiltrates usually are not present in the smooth muscle unless severe transmural esophagitis is present, which suggests that inflammation is not a cardinal feature of the pathogenesis of esophageal smooth muscle lesions in scleroderma.

**Figure 84-10** Oral manifestations. **A**, Perioral skin tightening with decreased oral aperture, furrowing around the lips, and dry membranes. **B**, Periodontal disease with regression of gum and loosening of teeth. **C** and **D**, Telangiectasias on the lips and tongue.

The severity of esophageal symptoms may not accurately reflect the seriousness of the underlying disease. Therefore, every patient with scleroderma should be fully evaluated for esophageal involvement. If untreated, GI reflux may lead to esophagitis, bleeding, esophageal strictures, or precancerous lesions such as Barrett's esophagus. Asymptomatic patients without abnormal laboratory test results (e.g., anemia or positive evidence of GI bleeding) do not require specific interventions. Patients with mild GERD can be treated empirically with proton pump inhibitors and then can be followed up clinically if they become symptom free with normal laboratory data. When more severe symptoms are present (e.g., GERD with dysphagia), or when treatment with proton pump inhibitors fails, an upper GI endoscopy is necessary to fully assess the anatomy of the esophagus and the extent of related disease. Direct endoscopy is appropriate to rule out Barrett's esophagus, stricture, or a site of uncontrolled esophagitis or bleeding. Barium swallow and cine-esophagography are sensitive tests for esophageal strictures. However, direct measurement of esophageal motility via esophageal manometry may be needed if the cause of symptoms such as atypical chest pain is unclear. Although complications from Barrett's esophagus (e.g., esophageal cancer) are uncommon, periodic repeat endoscopy to reassess status is recommended, even if symptoms are under therapeutic control.

It is critical that patients alter their eating behavior to complement medication therapy. Patients often experience better results by eating more frequent smaller meals, avoiding food intake for several hours before bedtime, moving the main meal toward midday, taking a walk after meals to help gastroesophageal emptying, and eliminating foods that aggravate symptoms (e.g., spicy sauces and caffeinated or carbonated beverages). Bedtime is often a time of severe reflux. The occurrence of reflux can be improved by avoiding filling the stomach at least 2 to 3 hours before bedtime and by elevating the head and trunk during sleep. Treatment of reflux by suppression of gastric acid with antacids or histamine-2 is helpful but overall disappointing in patients with scleroderma. Conversely, proton pump inhibitors (e.g., omeprazole and lansoprazole) can be very effective. Usually, long-term daily treatment is required. Higher doses may be used periodically for breakthrough symptoms. If symptoms are not controlled with recommended medication dosages, then a formal 24-hour ambulatory pH study may be necessary to determine whether persistent symptoms are due to uncontrolled acid reflux. A prokinetic drug (e.g., metoclopramide, domperidone, or erythromycin) should be added when symptoms of dysphagia or endoscopic findings of esophagitis are present despite the use of effective acid suppression. These medications tend to be effective during early disease but are less likely to help later in the presence

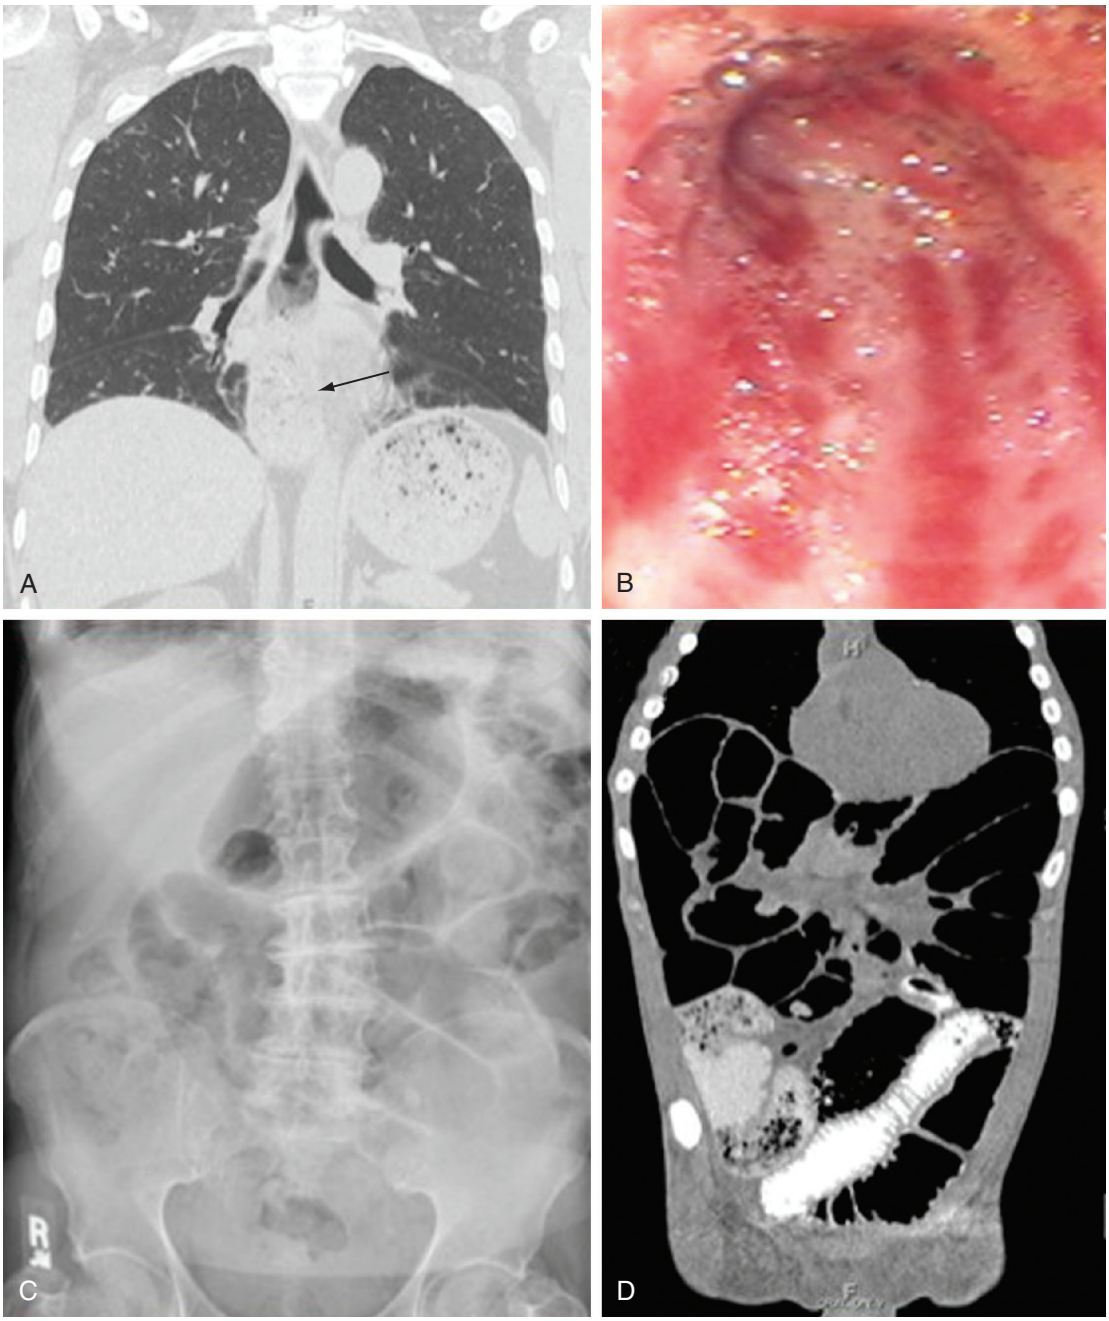

**Figure 84-11** Gastrointestinal manifestations in scleroderma. **A**, Chest computed tomography (CT) (sagittal view) showing severe esophageal dysmotility with dilation and *(arrow)* retention of gastric content. **B**, Upper endoscopy: gastric antral vascular ectasias presenting as "watermelon" stomach. **C** and **D**, Plain abdominal radiograph and abdominal CT: small intestinal dysmotility with pseudo-obstruction, pneumatosis cystoides intestinalis.

of advanced esophageal dysfunction. Many patients respond to relatively low doses, for example, at bedtime alone. Given the increased risk of neurologic complications with the use of metoclopramide, many clinicians recommend domperidone as a relatively safer alternative when long-term prokinetic treatment is needed. Domperidone should not be administered to subjects with pre-existing QT prolongation or in association with other drugs inhibiting CYP3A4 because of its arrhythmogenic potential.[85] Prucalopride, a selective high-affinity serotonin receptor agonist commonly used for constipation, has shown some benefit in subjects with GERD.[86]

### Stomach

The degree of delayed gastric emptying (gastroparesis) is underappreciated in scleroderma, and gastroparesis often causes early satiety, aggravation of GERD symptoms, anorexia, abdominal pain, a sensation of bloating, or nausea. Frequently, weight loss in patients with scleroderma is a consequence of poor caloric intake as a result of lack of appetite from poor gastric function. Prokinetics are used to improve gastric emptying and related symptoms, but results are generally disappointing. Gastritis or gastric ulcers can occur. Dilation of the microvasculature in the gastric mucosa

is found in a subset of patients. This manifestation, also called *gastric antral vascular ectasia* (GAVE), is thought to be caused by an abnormal angiogenesis, leading to bizarre dilation of microvessels and arterial-venous (A-V) malformations similar to the telangiectasias seen in the skin, lips, and oral mucous membranes. In general, these lesions are asymptomatic, but they can be responsible for occult GI bleeding. Extensive clusters of A-V malformations lead to the presence of longitudinal red stripes in the inner lining of the stomach, converging to the pylorus and described on endoscopy as "watermelon stomach," based on their appearance (Figure 84-11B). Endoscopic therapy with laser photocoagulation or cryotherapy can be used to ablate bleeding vessels. Rarely, bleeding associated with GAVE is refractory and requires multiple transfusions, repeated laser or cryotherapy, or even gastric surgery (e.g., antral or gastric resection).

### Lower Gastrointestinal Tract

Bloating, abdominal distention, diarrhea, and constipation are common complaints caused by dysmotility of the small and large bowel. Functional and pathologic studies again suggest that microvascular disease, neural dysfunction, smooth muscle atrophy, and tissue fibrosis similar to that seen in the esophagus are causing the bowel disease. Most cases present in similar fashion to irritable bowel syndrome. Constipation due to sluggish or atonic bowel function can result in repeated bouts of diarrhea with malabsorption, progressive loss of weight, and severe malnutrition. Diarrhea is thought to be caused by bacterial overgrowth as a consequence of bowel dysfunction, but other causes have been considered, including decreased mesenteric blood flow or pancreatic insufficiency. Recurrent episodes of pseudo-obstruction constitute one of the most serious intestinal problems in scleroderma. These episodes are sometimes mistaken for surgical emergencies. Pseudo-obstruction is a manifestation of profound loss of bowel smooth muscle function, causing severe dysmotility and segments of luminal dilation. Pneumatosis cystoides intestinalis sometimes complicates scleroderma of the bowel when gas leaks into the diseased intestinal wall and tracks into the mesentery of the gut or the peritoneal cavity, mimicking a bowel perforation (Figure 84-11C and D). Asymptomatic wide-mouthed diverticula, also resulting from fibrosis and atrophy of the bowel wall, are pathognomonic of scleroderma. Volvulus, stricture, and perforation are uncommon complications of severe bowel involvement.

Management of the lower GI tract includes avoiding a constipation-diarrhea cycle through adequate fiber ingestion, use of stool softener (docusate), or, if constipation is severe, periodic doses of osmotic laxatives (polyethylene glycol). Lubiprostone is helpful if chronic constipation predominates. Novel compounds are now available for chronic, refractory constipation such as prucalopride and linaclotide, but their efficacy in scleroderma has not yet been formally tested. Some experts also support the use of pyridostigmine in patients with scleroderma who have severe and persistent lower GI motility. Other prokinetic drugs are less effective for treatment of the lower GI tract. Octreotide is reported to help patients with severe lower GI hypomotility and pseudo-obstruction. In cases with bloating, recurrent bouts of diarrhea, or episodes of pseudo-obstruction, the use of cyclic antibiotics and/or probiotics is helpful. In some cases of intractable diarrhea, the use of cholestyramine is beneficial. Total parenteral nutrition may become necessary in patients with severe scleroderma-related bowel disease without response to other medical therapy. The presence of intestinal failure is a poor prognostic complication. Fecal incontinence can result in scleroderma caused by dysfunction of both internal (atrophy and fibrosis) and external (weakness) anal sphincters. Successful treatment includes firming stool texture, performing exercises to strengthen the pelvic muscles, providing biofeedback methods, and conducting surgical repair of aggravating factors such as rectal prolapse or severe hemorrhoids.

## Pulmonary Involvement

**KEY POINTS**

- **Lung disease is a major cause of morbidity and mortality in patients with scleroderma.**
- **Pulmonary fibrosis occurs in both limited and diffuse subsets of scleroderma, with a variable disease course in terms of severity and outcome.**
- **Nonwhite and antitopoisomerase 1–positive patients generally have the worst prognosis.**
- **Pulmonary function testing (spirometry and diffusing capacity) is helpful for screening and monitoring of ILD.**
- **The degree of lung fibrosis on high-resolution computed tomography predicts outcome.**
- **Current treatment for scleroderma-related ILD is limited to immunosuppression.**
- **Risk factors for pulmonary arterial hypertension include late onset of scleroderma, limited phenotype, and the presence of numerous telangiectasias.**

Pulmonary involvement is found in most patients with scleroderma. ILD and pulmonary hypertension are recognized as the most common lung complications and are now regarded as the major cause of death in scleroderma. In combination, it is estimated that they are responsible for 60% of scleroderma-related deaths.[26] They are present in many patients at the same time, but one process may dominate over the other. Lung disease can occur without symptoms, or it can cause progressive respiratory failure and severe limitation of the quality of life. Additional pulmonary complications such as chronic aspiration, pleural disease, spontaneous pneumothorax, neuromuscular weakness, drug-induced pneumonitis, and lung cancer need to be considered in the differential diagnosis of a patient with scleroderma who presents with respiratory symptoms.

### Interstitial Lung Disease

ILD, the most common lung manifestation, becomes clinically significant in up to 60% of patients with diffuse cutaneous scleroderma and in 20% of patients with limited skin disease. Higher risk of developing severe progressive ILD has been observed in patients with diffuse skin involvement, African-Americans, Native-Americans, and those

positive for antitopoisomerase 1 (Scl-70), anti-U3-RNP, or anti-Th/To antibodies. Data from a recent study of patients with active lung disease show that patients with limited scleroderma and those with diffuse scleroderma were indistinguishable with regard to their baseline pulmonary functions, although patients with limited skin disease presented with more extensive pulmonary fibrosis, perhaps reflecting a delay in diagnosis and more advanced progression of lung disease before study entry.[87]

ILD typically manifests with declining lung volumes and increased parenchymal fibrosis with reticular interstitial thickening that is greatest at the lung bases. Pathologic studies have shown that the most common histologic pattern of fibrosing alveolitis in scleroderma is nonspecific interstitial pneumonia (NSIP), as opposed to usual interstitial pneumonia (UIP), which is the common presentation of idiopathic pulmonary fibrosis. A mixed pattern of NSIP and UIP can also be found. The histopathologic classification does not appear to predict outcome, which is related to a greater degree to baseline disease severity and functional respiratory measures.[88] For this reason, a surgical lung biopsy is not required in the setting of patients with scleroderma who are experiencing a typical disease course. Although ILD is usually characterized by a functional restrictive ventilatory defect with reduced gas exchange, at later stages of the disease, some degree of airway obstruction can be found in association with honeycombing of lung parenchyma and bronchiectasis. Pleural reactions are not common in scleroderma. Rare cases of spontaneous pneumothorax, adult respiratory distress syndrome, and pulmonary hemorrhage have been reported. Aspiration as a result of GERD, secondary infection, and heart failure can complicate the course of scleroderma lung disease. Some investigators consider GERD associated with chronic aspiration to be a potential inciting factor for the development of ILD in scleroderma.[89]

During earlier stages of ILD, the underlying active fibrosing alveolitis may be totally asymptomatic and may not be detected by conventional chest radiographs. The most common symptoms of scleroderma lung disease are dyspnea (initially upon exertion) and fatigue. Chest pain is not typical, and nonproductive cough is usually a late complication, particularly in association with the presence of traction bronchiectasis. Coughing in patients with scleroderma often is not the result of a primary lung problem but rather is a manifestation of GERD with associated laryngeal irritation. The most characteristic finding of ILD on physical examination is bilateral fine inspiratory crackles (i.e., "Velcro" rales) at the lung bases. Pulmonary function testing (PFT) is the method most commonly used to detect ILD (Figure 84-12). The earliest functional abnormality is a reduction in the single breath diffusion capacity of carbon monoxide (DLCO). Although a decline in DLCO correlates with the severity of pulmonary fibrosis as measured by HRCT and predicts worse outcome, it is not a very specific measure and also can be abnormal in the context of

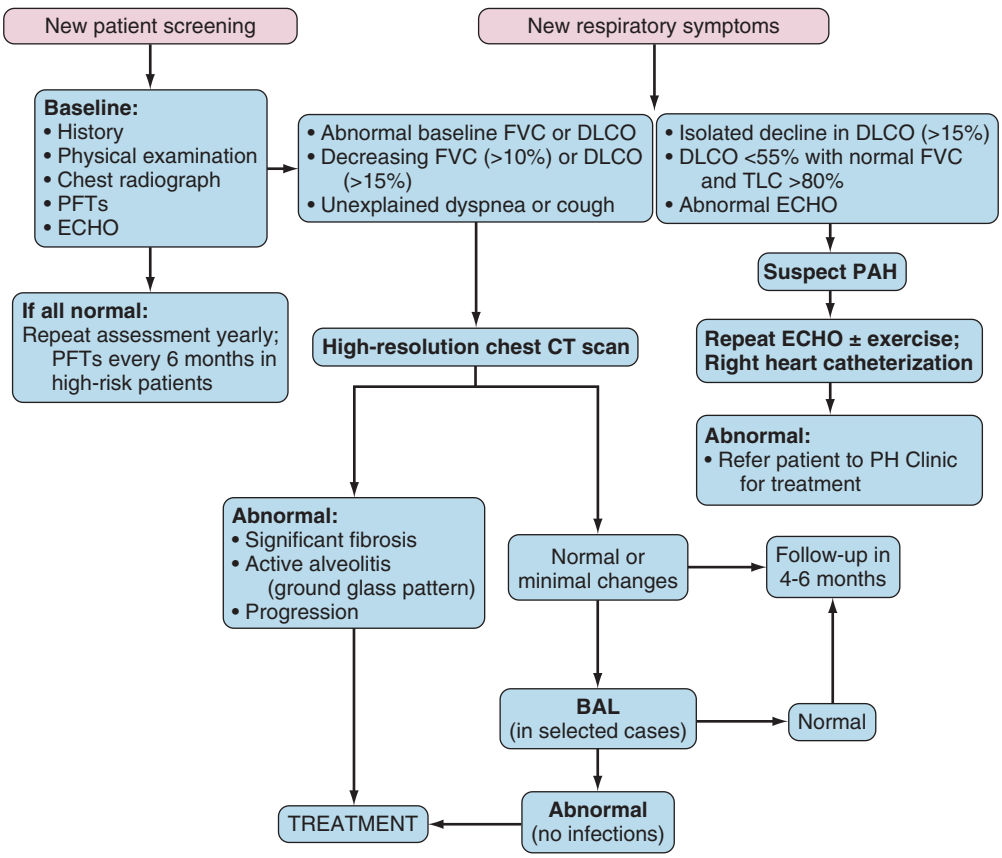

**Figure 84-12** Approach to lung disease in scleroderma. This approach is recommended for all patients with scleroderma who have both new-onset and long-standing disease. BAL, Bronchoalveolar lavage; CT, computed tomography; DLCO, diffusing capacity; ECHO, echocardiography; FVC, forced vital capacity; PAH, pulmonary arterial hypertension; PH, pulmonary hypertension; PFT, pulmonary function test; TLC, total lung capacity.

pulmonary vascular disease and underlying chronic obstructive disease/emphysema. A restrictive ventilatory defect is identified by a depression of the forced vital capacity (FVC) and the total lung capacity. The most reliable tool for monitoring ILD over time is serial measurements of FVC. A decline in FVC of more than 10% from baseline is often indicative of disease activity and is associated with increased mortality. The course of lung disease may remain stable or exhibit worsening after variable intervals (months or years) of unchanged lung function. In some cases, progression is invariable and rapidly leads to end-stage lung disease. Patients presenting with a normal FVC during early stages of scleroderma have a better lung prognosis, and an early reduction in FVC is likely to be associated with further progression of lung involvement, usually within the first 2 to 4 years from disease onset. The presence of ILD predicts increased mortality. One study found that patients with severe ILD have a 9-year survival rate of approximately 30%, whereas patients with no severe organ involvement have a 72% survival rate.[26] The most rapid decline in FVC is thought to occur within the initial 3 years from disease onset, but progression of ILD can occur in later years, so it is recommended that respiratory status be monitored on a regular basis and that pulmonary function be tested yearly.

HRCT is more accurate than chest radiography in evaluating diffuse lung disease; it is a well-established, sensitive, and noninvasive method of detecting and characterizing ILD in persons with scleroderma. The extent of pulmonary fibrosis on HRCT correlates closely with PFT abnormalities and can be used to predict prognosis.[90] Recent evidence shows that the degree of HRCT changes coupled with the level of lung function deficit can be used to generate a simple staging system (limited vs. extensive disease) with good prognostic value.[91] An FVC of less than 70% or a disease extent according to HRCT of greater than 20% predicts ILD progression and higher mortality. HRCT features of fibrosis are present in 55% to 65% of all patients with scleroderma and in almost every patient with abnormal pulmonary function tests. The earliest and most common abnormality on HRCT is usually found in the posterior and basilar portion of the lungs in the form of increased subpleural lung attenuations in the absence of distinct architectural distortion. With progression of the disease, increased "ground glass" opacities are seen, but it has been well established that these changes alone are not always indicative of active inflammation, nor can they predict progression itself. Subsequent detection of a fine reticular pattern often precedes overt pulmonary fibrosis manifested by parenchymal distortion, reticular intralobular interstitial thickening, traction bronchiectasis and bronchiolectasis, and, in the late stages, honeycomb and cystic air spaces (Figure 84-13). When reticular interstitial abnormalities are present on HRCT, regression of disease rarely, if ever, occurs.

Pathologic studies of patients with scleroderma who have early lung disease have shown that lung fibrosis is preceded by the presence of a mixed interstitial inflammatory infiltrate spilling into the alveolar spaces (alveolitis). It has been assumed that measuring abnormal levels of inflammatory cells in the bronchoalveolar lavage (BAL) would allow identification of patients with active lung disease who are at risk for progression and would potentially benefit from immunosuppressive therapy. Published data have shown that an abnormal BAL cell count, in particular with increased granulocytes (neutrophils and eosinophils), is associated with more severe lung disease and mortality in patients with scleroderma-related ILD.[92] However, the value of BAL cytology in predicting lung disease progression or response to treatment has not been uniformly confirmed. Few observational studies have indicated that the presence of BAL granulocytic alveolitis was associated with significant deterioration of lung function tests over time in patients who were not receiving immunosuppressive therapy.[93] In contrast, other studies did not find a clear association between BAL cellular abnormalities and clinical outcomes.[94] At present, evidence to recommend routine clinical use of BAL cytology to predict outcome in patients with scleroderma and ILD is still insufficient. Other biomarkers have been investigated to monitor the activity and progression of ILD more accurately, but they are not yet available for routine clinical use. Markers of alveolar cell damage such as KL-6 or surfactant proteins A (SP-A) and D (SP-D) are increased in the serum of patients with scleroderma who have active ILD and predict survival.[95,96] Increased levels of pro-inflammatory molecules such as CCL-18 or IL-6 are also associated with declining lung function and worse outcome.[97,98]

Early detection and prompt therapeutic intervention remain essential in preventing progression of lung disease. Current treatment of scleroderma-related ILD is most often directed against the immune response and the inflammatory process mediating lung injury and tissue fibrosis. A randomized placebo-controlled study comparing 1 year of oral cyclophosphamide (CYC) versus placebo suggests some modest benefit of the active drug (improvement in FVC).[87] This benefit was sustained at 18 months but was completely lost after 2 years' follow-up, suggesting that a sequential or maintenance immunosuppressive approach may be indicated to retain the clinical response. Other studies suggest that use of IV monthly CYC followed by azathioprine (AZA) as maintenance therapy provides benefits. Several small retrospective studies have shown moderate benefit from mycophenolate mofetil (MMF) with improvement in or stabilization of lung function, suggesting that this drug may prove to be a safe and effective treatment in patients with scleroderma and a possible alternative to CYC. Although more studies are needed to confirm the benefit of immunosuppressive therapy in scleroderma-associated ILD, newer drugs are under investigation, including targeted biologic immunotherapies and antifibrotic molecules (see section on Therapeutic Approach for Disease Modification). More aggressive immunosuppressive protocols such as autologous or allogeneic hematopoietic stem cell transplantation, preceded by myeloablative or immunoablative conditioning regimens, are under investigation, but their treatment toxicity remains a concern.

It remains very important to pursue careful selection of patients and to treat only those with evidence of active lung disease. In fact, in most cases, no or minimal progression to severe disease is seen despite some evidence of underlying pulmonary fibrosis. Selection of patients who require treatment is best performed with serial studies and careful assessment of both pulmonary function tests and HRCT scans.

Lung transplantation is an option in patients with severe ILD who are not responsive to medical therapy. Carefully

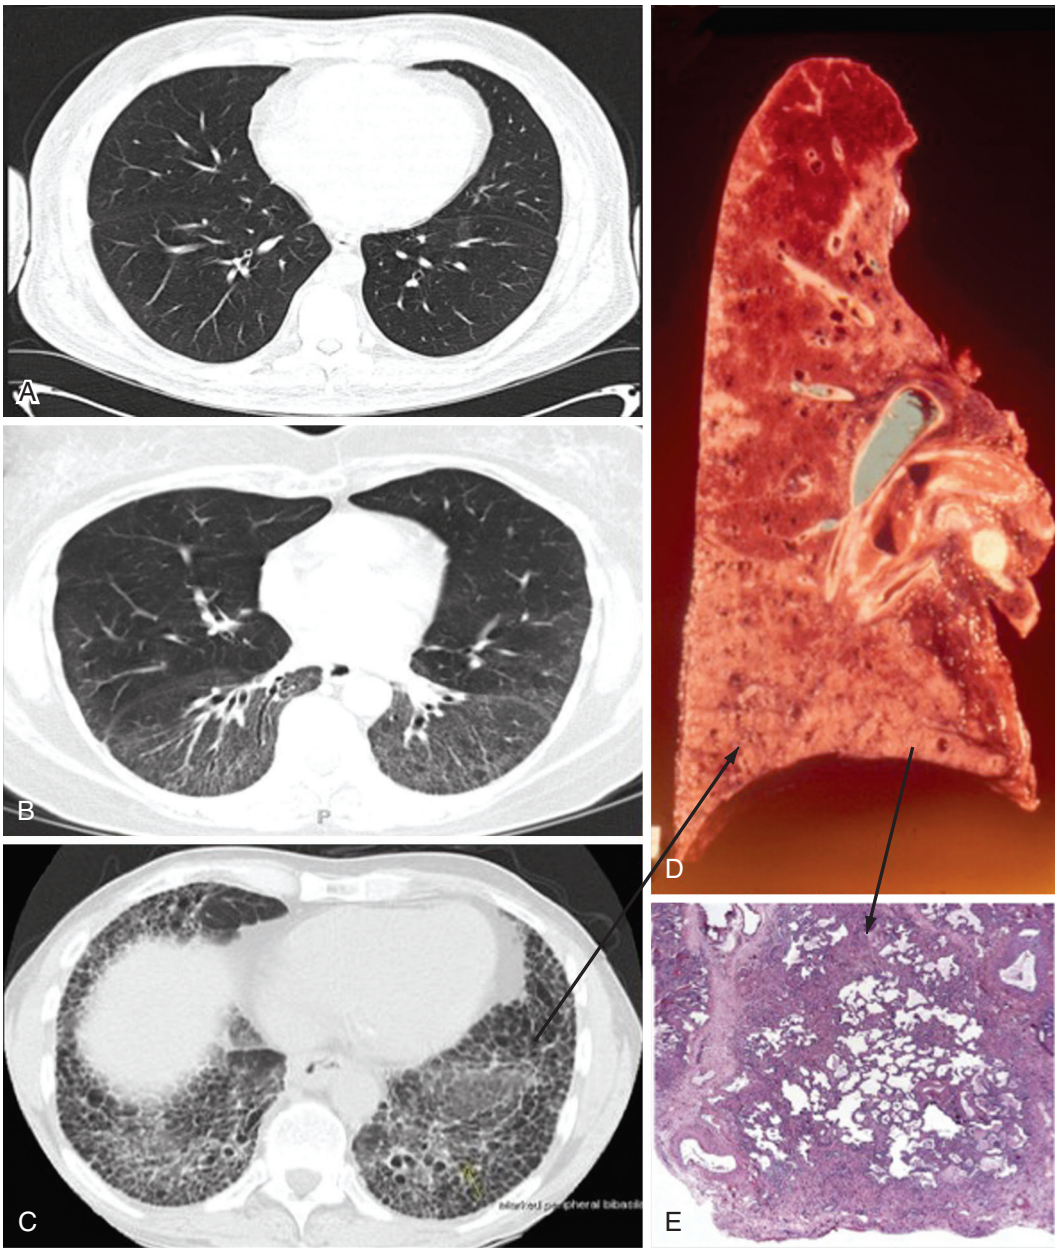

**Figure 84-13** Scleroderma-related interstitial lung disease: high-resolution chest computed tomography scan showing **(A)** normal lung, **(B)** active alveolar inflammation ("ground glass" opacification), and (**C)** end-stage lung disease with honeycombing. **D**, Gross pathology. **E**, Histology showing fibrosing alveolitis.

selected patients with scleroderma who undergo lung transplantation have similar morbidity and mortality as patients undergoing transplantation for idiopathic lung disease.[99,100] A retrospective survey of 47 patients with scleroderma who underwent lung transplantation found that 1- and 3-year survival rates were 68% and 46%, respectively.

### Pulmonary Hypertension

Pulmonary arterial vascular disease is a common manifestation of scleroderma; when associated with PAH, it represents a difficult clinical challenge with life-threatening consequences. The pulmonary vascular process can be indolent and remain clinically silent, or it may lead to respiratory distress as a result of severe PAH and associated right heart failure. Typical symptoms associated with clinically manifested PAH include dyspnea upon exertion, fatigue, and, less commonly, chest pain or syncope. Physical examination may be normal during early stages of PAH, but as the disease progresses, a systolic murmur of tricuspid regurgitation, a loud pulmonic component, the S2, an S3 gallop, and signs of right heart failure (e.g., right-sided parasternal heave, prominent and elevated jugular venous pulse, hepatomegaly, and signs of fluid overload with peripheral edema) are seen. Later in the disease, patients become dyspneic with little activity, have a resting tachycardia, and may appear cyanotic. Sudden syncope or death can occur as a result of hypoxia and congestive heart failure.

PAH is usually a late complication of scleroderma, typically manifesting after 10 years from disease onset, particularly in patients with limited cutaneous involvement. However, it is becoming more evident that in some patients this condition may develop early and remain undetected. A study of a French scleroderma cohort identified a substantial proportion of patients in whom PAH actually developed within 5 years from disease onset.[101] Considering the potentially devastating consequences of PAH, early diagnosis is very important. Simple bedside examination is not very sensitive, particularly during early stages, and thus it is recommended that every patient with scleroderma be screened using objective testing such as electrocardiography (ECG), ECHO, and pulmonary function testing (Figure 84-14). Proper initial workup also should aim at excluding chronic thromboembolic disease and the possibility of underlying obstructive sleep apnea. The ECG can be normal, but as disease progresses, signs of right-sided heart strain with right ventricular hypertrophy and right axis deviation can be observed. Detection by ECHO of increased right ventricular systolic pressure (RVSP) is useful, but values need to be confirmed by right heart catheterization (RHC), given the possibility of false-positive or false-negative results. When the ECHO estimates an RVSP greater than 45 mm Hg about 95% of the time, this finding will be confirmed by RHC.[102] Some clinicians use the tricuspid gradient as a measure of pulmonary artery pressure. Additional noninvasive screening includes pulmonary function testing. A low diffusing capacity (DLCO) without evidence of obstructive or restrictive lung disease (low FVC) suggests a defect in gas exchange as a result of pulmonary vascular disease or PAH. DLCO may progressively decline for years before the diagnosis of PAH is established.[103] Increased serum N-terminal pro-brain natriuretic peptide (NT-proBNP) may indicate the presence of PAH and right heart strain, even when levels are modestly elevated (>395 pg/mL).[104] The diagnosis of PAH should be confirmed by RHC, providing direct measurement of pulmonary hemodynamics. PAH is defined as resting mean pulmonary arterial pressure equal to or greater than 25 mm Hg, with normal pulmonary capillary wedge pressure equal to or less than 15 mm Hg. In addition to confirming abnormal hemodynamic values, the RHC can help in differentiating true PAH from pulmonary venous hypertension as a result of left heart failure or pulmonary

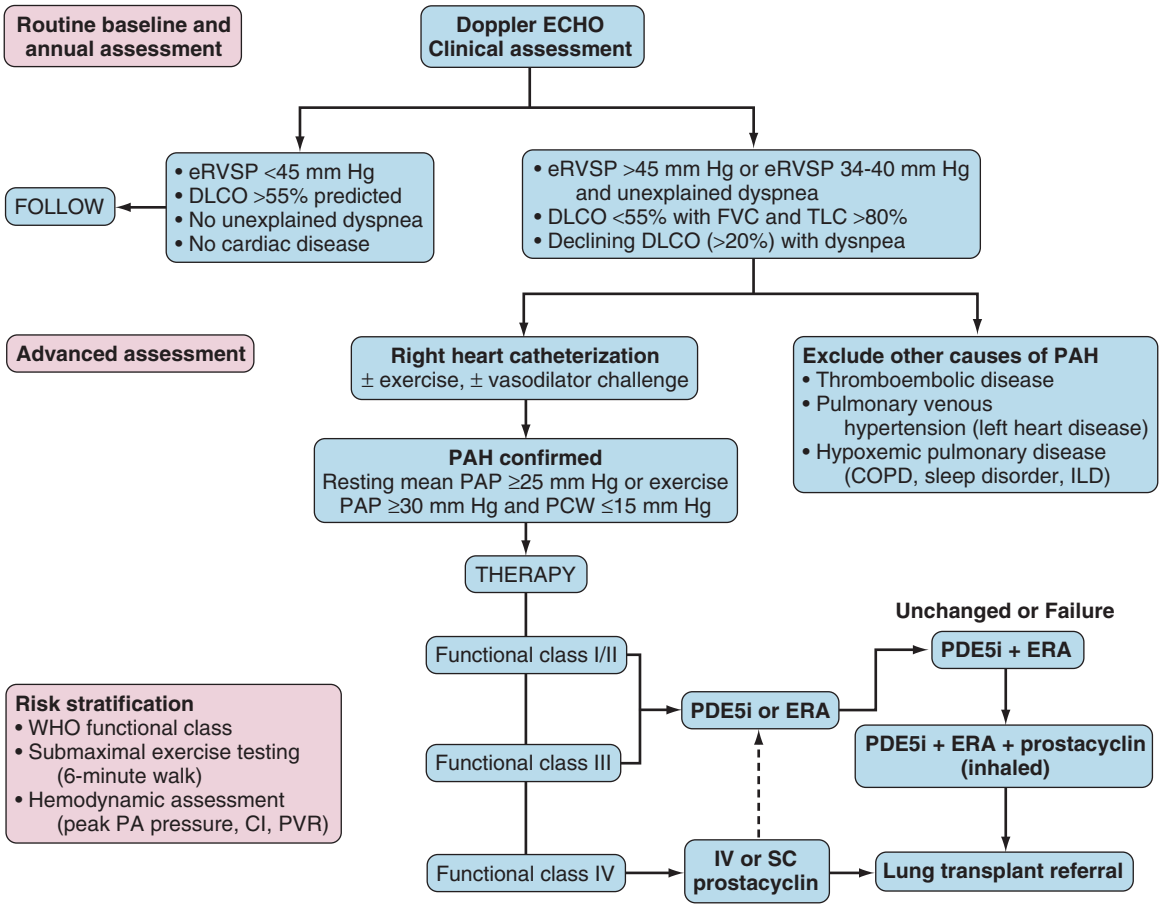

**Figure 84-14** Approach to scleroderma-associated pulmonary arterial hypertension (PAH). This approach is recommended for all patients with scleroderma who have new-onset disease or especially long-standing disease with limited scleroderma. Increasing WHO functional class reflects more severe symptoms and greater restriction in activity.

occlusive disease. The 6-minute walk test can provide baseline functional information but cannot accurately assess the severity of PAH. Because baseline hemodynamic parameters do not correlate well with the clinical course of PAH in patients with scleroderma, new cardiopulmonary dynamic testing such as exercise stress ECHO and exercise during RHC have been introduced, but their role in diagnosing or monitoring PAH has not yet been fully established.

Based on the definition and the tools used to obtain measurements, the prevalence of PAH in patients with scleroderma has been reported with variability. Using ECHO as a diagnostic tool, the prevalence of PAH has been estimated at between 30% and 50% of all studied patients, and investigations using confirmatory RHC have detected a prevalence of 8% to 12%.[105,106] Clinically, scleroderma-related pulmonary vascular disease can present in three different ways. In some patients, it manifests and progresses as severe isolated PAH in the absence of other significant lung disease. In other patients, it can be associated with mild or severe pulmonary fibrosis that is believed to drive vascular disease and PAH by causing chronic hypoxia coupled with destruction of lung parenchyma and underlying vasculature. Association of ILD and PAH usually entails a worse prognosis. In a third group of patients, pulmonary vascular disease presents with dyspnea upon exertion, isolated decline of the DLCO with no significant signs of ILD (i.e., low lung volumes), and a normal resting ECHO and/or RHC. These patients are considered to have microvascular lung disease and may be at high risk of developing overt PAH. Increased risk of developing PAH has been associated with limited skin disease, late age at onset of scleroderma, the presence of numerous telangiectasias, low DLCO, and the presence of anti-U3-RNP antibody. Some studies suggest that the presence of anticentromere, anti-B23, and anti–$\beta_2$-glycoprotein I antibodies also increases the risk for PAH.

PAH has a major impact on quality of life and survival of affected patients. The natural course of the disease is characterized by progression of hemodynamic impairment, resulting in right heart failure and leading to a poor outcome. Despite the availability of newer targeted therapies, the median survival in patients with scleroderma who have PAH ranges between 1 and 3 years.[107,108] A progressive rapid increase in pulmonary pressure is more likely to occur in patients with limited skin disease and late age at the onset of scleroderma.[109] This more aggressive course is associated with high mortality. Survival in patients with ILD-associated PAH is significantly worse (a 3-year survival of 46%) than in patients with PAH alone (a 3-year survival of 64%).[110] This difference is possibly explained by the presence of underlying comorbidities in scleroderma, and in particular of biventricular heart (myocardial) involvement. A 10-fold increase in NT-proBNP blood levels is associated with higher mortality.[111,112] ECHO findings can help predict prognosis. For example, the degree of tricuspid annular plane systolic excursion (TAPSE) reflects right ventricular function. A TAPSE of less than 1.8 cm is associated with decreased survival in patients with PAH.[113] A recent survey identified that pulmonary vascular resistance, stroke volume index, and pulmonary arterial capacitance were strong predictors of survival.[114] This finding suggests that right ventricular dysfunction is associated with poorer outcome. Male gender and higher New York Heart Association functional class also have a negative impact on prognosis. It is suggested that survival has improved with current modes of therapy. One survey found a 2-year survival rate of 47% in historical control subjects as opposed to a rate of 71% among patients treated with modern therapy.[115]

All patients with PAH are encouraged to continue an active lifestyle as tolerated. Formal educational and exercise programs can improve their quality of life. Conventional therapy includes diuretic therapy (loop and potassium-sparing diuretics) and supplemental oxygen therapy if needed. Anticoagulation is used if there is no defined risk for bleeding. Although calcium channel blockers may help patients with evidence of acute vasodilative response during hemodynamic testing, this finding is uncommon in scleroderma. In recent years, a number of targeted agents have become available for the treatment of PAH. Many clinical trials testing these drugs in primary PAH have included about 20% of patients with connective tissue disease, primarily scleroderma. Specific therapies include prostaglandin derivatives (e.g., epoprostenol, treprostinil, beraprost, and iloprost), endothelin receptor antagonists (e.g., bosentan, sitaxsentan, ambrisentan, and macitentan), phosphodiesterase-5 inhibitors (e.g., sildenafil, tadalafil, and vardenafil), and a soluble guanylate-cyclase stimulator (riociguat). Inhaled prostaglandins can be an option in severe cases. These drugs can improve hemodynamics, exercise tolerance, and quality of life. No evidence from clinical trials exists to suggest that any one of these agents is superior to another, but evidence suggests that prostacyclin therapy is the most effective for severe PAH. Most clinicians believe that early intervention is most important because it leads to better outcomes and that combination therapy may be helpful (see Figure 84-14). The use of prostaglandin therapy should be considered immediately in people with more severe PAH. Decisions regarding the preferred agents to use and how to deliver them are based mostly on personal preferences and the clinical status of the individual patient. For patients with mild to moderate disease (functional class I or II), treatment with a single oral agent is usually initiated (i.e., sildenafil, bosentan, or ambrisentan). Our preference is to use sildenafil, given its favorable adverse effect profile. Patients presenting with more severe disease (class III or IV) and those who do not respond to monotherapy are usually treated with IV or inhaled prostaglandins alone or in combination with one or two oral agents. Sildenafil and bosentan can be used in combination, even if concern arises about their interaction and increased hepatotoxicity.[116,117] Lung or heart-lung transplantation for PAH remains the treatment of last resort when medical therapy fails. Patients with scleroderma who are carefully selected for transplantation have an outcome that is similar to patients with other causes of lung disease. PAH in scleroderma is a progressive disease for which no specific or single therapy may suffice. Therefore, careful longitudinal monitoring is important. Noninvasive testing with periodic clinical assessment with the 6-minute walk time, repeat pulmonary function testing, and ECHO studies are helpful. When a major therapeutic decision is needed, such as switching to or adding a new therapy, a repeat RHC may be indicated. Further improvement in survival of patients with scleroderma who have PAH may result from future therapeutic interventions targeting the underlying inflammatory process and the dysregulated

endothelial proliferation that mediates pulmonary vascular remodeling and consequent failure of the right heart.

## Cardiac Involvement

The clinical manifestations of heart disease are highly variable, ranging from clinically silent cardiac involvement to frank heart failure. The reported prevalence of heart disease varies from 10% to more than 50%, depending on the diagnostic method used, but in general it tends to be underestimated. Symptoms such as dyspnea, chest pain, or palpitations are commonly thought to be the result of more obvious organ involvement such as the lungs or the upper GI tract, and the contribution of heart disease often is not appreciated until later stages. Cardiac disease can occur in both diffuse and limited subtypes of scleroderma and can manifest as a primary heart problem or in association with other organ failure. When clinically evident, heart disease entails an overall poor prognosis and predicts shortened survival.[118] Along with pulmonary fibrosis and PAH, cardiac disease accounts for the majority of deaths in scleroderma. One study found that 25% of deaths could be directly related to heart disease (mostly heart failure and arrhythmias).[19] In a large meta-analysis, cardiac involvement was associated with increased mortality (hazard ratio, 2.8; 95% CI, 2.1 to 3.8) after adjustments for age and gender.[119] A survey comparing 129 patients with scleroderma who had a left ventricle ejection fraction (LVEF) of less than 55% with 256 subjects who had a normal LVEF demonstrated that male gender, age, digital ulcerations, myositis, and no use of calcium channel blockers were independent factors associated with left ventricular dysfunction.[120]

Cardiac disease in scleroderma can be characterized by involvement of the endocardium, myocardium, and pericardium, separately or concomitantly. As a consequence, pericardial effusion, auricular and/or ventricular arrhythmias, conduction disease, valvular regurgitation, myocardial ischemia, myocardial hypertrophy, and heart failure are all reported. Clinically overt pericarditis is uncommon, but asymptomatic and hemodynamically benign pericardial effusions are frequently detected by ECHO. In a controlled study, significant pericardial effusion was found in about 15% of patients compared with 4% of control subjects.[121] Pathologic studies have shown that some degree of pericardial involvement is detectable in 33% to 77% of patients with scleroderma, usually with evidence of a fibrinous pericarditis with adhesions and chronic inflammatory cell infiltrates.[122] Hemodynamic compromise resulting from tamponade physiology is rare but may require acute intervention with antiinflammatory medication, pericardiocentesis, or creation of a pericardial window for slow decompression. The presence of a large pericardial effusion, even if it is asymptomatic, is a poor prognostic sign, particularly if it is associated with PAH or renal disease.

Focal myocardial fibrosis is the hallmark of established primary heart involvement in scleroderma. Studies have provided controversial data regarding increased risk for atherosclerotic coronary artery disease. Although pathologic studies and an analysis of coronary angiograms have found little involvement of coronary arteries in patients with scleroderma, epidemiologic surveys seem to indicate an increased risk of atherosclerosis in this disease, similar to other rheumatic conditions such as rheumatoid arthritis or systemic lupus erythematosus.[7,24,123] Therefore, typical angina symptoms should make one consider atherosclerosis of the coronary vessels or another process. Atypical chest pain can also be caused by musculoskeletal problems, esophageal reflux disease, or PAH mimicking cardiac disease. The fibrotic lesions in the hearts of patients with scleroderma are patchy, involve the myocardium of both ventricles, and usually are accompanied by evidence of microvascular disease with concentric intimal hypertrophy associated with fibrinoid necrosis of the intramural coronary arteries and arterioles.[124] This phenomenon results in reduced coronary flow reserve even with normal epicardial coronary arteries and in the absence of clinically manifested cardiac dysfunction.[125] Vasospasm and associated myocardial perfusion defects are demonstrated to occur at rest, with exercise, and after exposure to cold temperatures.[126] These findings suggest that myocardial fibrosis may be associated with reversible vasospasm of the microvascular coronary circulation and that vasodilating agents such as calcium channel blockers may have the capacity to improve coronary flow and prevent further cardiac damage.[127] Patients with angina-like chest pain may need to undergo angiographic studies because nuclear perfusion studies are likely to be abnormal as a result of microvascular disease.

ECG and Holter monitoring often show some heart conduction defect or asymptomatic arrhythmia, which are thought to be consequences of myocardial fibrosis. Premature ventricular contractions are the most common abnormality, but sinus node dysfunction, first-degree heart block, supraventricular arrhythmias (supraventricular tachycardia and atrial fibrillation), and ventricular arrhythmias (ventricular tachycardia) are also observed. Complete heart block is uncommon. Scleroderma-related syncope is an ominous manifestation of late-stage PAH or an important arrhythmia. When an arrhythmia is suspected, a Holter monitoring study should be ordered promptly. More extensive evaluation with electrophysiologic studies is indicated in serious cases because a pacemaker or ablative therapy can help in the management of these life-threatening complications. In subjects with documented advanced cardiomyopathy and significant ejection fraction depression, placement of an automatic implantable cardioverter defibrillator device should be considered to prevent sudden cardiac death.[128]

Transthoracic ECHO (TTE), a widely used type of noninvasive cardiac testing, is a sensitive tool to detect the presence of cardiac disease. TTE can provide estimates of elevated right ventricular (RV) and pulmonary artery pressures, as well as evidence of right heart dysfunction such as atrial and ventricular dilation or septal wall motion abnormalities. A depressed left ventricular (LV) contractility is not frequently detected in patients with scleroderma with the use of conventional TTE, but relaxation abnormalities can be found in up to 40% of cases.[129] LV diastolic dysfunction is detected, especially in patients with diffuse scleroderma, and it may occur in the absence of systemic hypertension (independent of renal disease) and in association with pulmonary vascular disease. Although TTE is very helpful in monitoring underlying cardiac abnormalities later in the disease process, it lacks some sensitivity during preclinical stages of heart involvement. Novel diagnostic methods such as tissue Doppler ECHO, with or without

strain imaging, and MRI that have been applied more recently to study myocardial disease in scleroderma have shown the ability to detect abnormalities earlier than conventional ECHO and with greater accuracy.[130,131] Provocative exercise testing during ECHO can be used to detect underlying diastolic dysfunction and pulmonary hypertension not previously recognized by resting studies.

Cardiac evaluation has been improved by the systematic measurement of brain natriuretic peptide (BNP) or its prohormone NT-proBNP. Blood levels of NT-proBNP reflect both RV and LV volume or pressure overload. It can be a useful test and a prognostic marker to follow up on right or left heart failure in patients with scleroderma.[112,132] No formal studies have been conducted to measure serum levels of troponin in relationship to scleroderma cardiac involvement. However, this test can help identify patients with ongoing myocardial injury.[133]

Patients with diffuse cutaneous scleroderma and skeletal muscle inflammation (polymyositis) are particularly prone to the development of severe cardiomyopathy and to have a particularly poor prognosis. Acute myocarditis can in fact occur in association with inflammatory muscle disease and can present as sudden-onset heart failure. Prompt institution of immunosuppressive treatment is indicated in these cases. A cardiac MRI and/or an endomyocardial biopsy may be helpful tools to differentiate overt myocarditis from the myocardial fibrosis commonly present in patients with scleroderma. It is not clear whether antiinflammatory treatment is indicated for small, stable, and asymptomatic pericardial effusions. In selected cases, NSAIDS or colchicine may be helpful. The potential cardiotoxicity of colchicine may be a limitation for its use in patients with scleroderma who have myocardial involvement.

## Renal Involvement

**KEY POINTS**

- **Scleroderma renal crisis (SRC) is a life-threatening condition that occurs in 5% to 10% of patients with scleroderma.**
- **Risk factors for SRC include early diffuse skin disease, use of corticosteroids, and the presence of anti-RNA polymerase III antibodies.**
- **Early pharmacologic intervention with ACE inhibitors is crucial to control and possibly reverse the disease process.**

Renal involvement in scleroderma is classically characterized by the abrupt onset of very high blood pressure (malignant hypertension), elevated plasma renin, and rising serum creatinine reflective of acute renal failure, along with a constellation of symptoms and clinical manifestations such as headaches, malaise, hypertensive retinopathy, encephalopathy, and pulmonary edema, usually referred to as *scleroderma renal crisis* (SRC). Renal disease in scleroderma can also be asymptomatic, and despite the high prevalence of histopathologic renovascular lesions typical of scleroderma vasculopathy, clinically important renal dysfunction, independent of SRC, is seen in only a minority of patients.[134] Although SRC is the most recognized renal complication, abnormal renal function can be explained by factors other than intrinsic scleroderma renal disease such as medication adverse effects, comorbid conditions, or associated heart, GI, or lung disease. One survey suggested that mild unexplained proteinuria without loss of renal function or evidence of glomerular disease is a common sign of renal disease in scleroderma.[135] A superimposed inflammatory kidney disease can also occur. Several cases of pauci-immune necrotizing crescentic glomerulonephritis associated with myeloperoxidase-specific ANCAs have been reported in patients with scleroderma who have a presentation mimicking SRC.[136]

SRC needs to be considered in patients with scleroderma who have sudden and severe elevation of blood pressure, with or without renal failure; in patients with sudden renal failure, with or without hypertension; and in patients with sudden-onset microangiopathic hemolytic anemia, with or without hypertension or renal failure. Nonmalignant hypertension alone without signs of renal dysfunction or mild urine abnormalities is unlikely to be due to SRC. SRC occurs in 5% to 10% of patients, mostly in those with diffuse scleroderma. It is usually encountered within the first 2 to 4 years from disease onset. The estimated median duration of scleroderma at the time of SRC diagnosis is 8 months.[137,138] Occurrence in later disease is uncommon.[108] Patients at greatest risk of developing SRC are those with diffuse cutaneous scleroderma, particularly those who have the rapidly progressive skin disease. SRC is a rare complication in patients with limited scleroderma (approximately 1% to 2%). African-Americans and patients with diffuse skin disease who are treated with a high dose of corticosteroid (>40 mg/day of prednisone) or low-dose cyclosporine are at increased risk of developing an SRC. A long-term low dose of prednisone may also be a risk factor for SRC. For this reason, it is recommended that use of corticosteroids be avoided or that doses less than 15 mg daily be used if necessary. Renal crisis is also associated with a positive ANA (speckled pattern) anti-U3-RNP and usually is not seen in patients with anticentromere antibodies. Antibodies to RNA polymerase III were found in about 60% of patients with SRC in one survey.[137] Although antitopoisomerase I antibodies are prevalent in patients with diffuse skin disease, no association between their presence and SRC has been reported. Nonmalignant hypertension, abnormal urinalysis, and isolated increases in plasma renin activity are not predictors of an SRC.[139]

Patients experiencing SRC present with typical signs of malignant hypertension, including headache, altered vision, signs of congestive heart failure, florid pulmonary edema, confusion, or neurologic signs as a result of hypertensive encephalopathy in the setting of an abnormally high blood pressure, usually greater than 150/90 mm Hg. Hypertensive encephalopathy is characterized by acute or subacute onset of lethargy, fatigue, confusion, headaches, visual disturbances (including blindness from hypertensive retinopathy), seizures, or cerebral hemorrhage. In about 10% of cases, SRC occurs with normal blood pressure. New-onset anemia, asymptomatic pericardial effusion, and cardiac disease may precede an SRC. Laboratory testing at onset may show normal or high creatinine, modest to absent proteinuria, and/or microscopic hematuria. Renal insufficiency usually is not the presenting problem in an SRC but rather is a late complication of untreated disease. However, a rapid rise in serum creatinine can occur over

several days with a fairly benign urinalysis—less than 2 g of protein excretion in 24 hours—and a mild hematuria with some granular casts. A microangiopathic hemolytic anemia and thrombocytopenia can accompany or precede an SRC and may be the only finding in a normotensive patient. This presentation with normotensive SRC usually entails a worse prognosis. Distinguishing SRC-associated thrombotic microangiopathy from idiopathic thrombotic thrombocytopenic purpura may be difficult but is important because treatments differ. Accurate assays for ADAMTS (a disintegrin and metalloproteinase [ADAM family] with thrombospondin-1 domains)-13 activity can be helpful because its level should be normal in scleroderma.

Poorer outcome is more frequent among males and among patients presenting with creatinine greater than 3 mg/dL (265 mmol/L). Approximately two-thirds of patients with SRC will require renal support with dialysis, but about half will recover function and be able to discontinue therapy, usually within several weeks, and most before 6 months.[137] However, cases of recovery from up to 24 months of dialysis support have been reported, distinguishing SRC from other causes of renal failure. The renal crisis truly mimics malignant hypertension, with rapidly progressive renal failure as a result of microvascular disease, vasospasm, and tissue ischemia. The characteristic lesion of vascular disease such as intimal hyperplasia or luminal narrowing involving in particular the renal arcuate arteries is detected even in patients without SRC. Although the renal disease is now well described, the pathogenesis of the renal crisis remains poorly understood. It is assumed that intrinsic renal vessel disease is complicated by an intense vasospasm triggering high levels of plasma renin, which results in malignant hypertension.

Before the discovery of ACE inhibitors, hypertensive renal crisis almost uniformly had a fatal outcome. In contrast, patients treated with ACE inhibitors have a good outcome 60% of the time, and death or end-stage renal disease is now much less common. The mortality rate at 1 year associated with SRC has decreased from 76% to less than 15%. However, despite aggressive anti-hypertensive therapy, the 5-year survival of patients with SRC remains only 65%. Although ACE inhibitors are standard therapy for SRC, it remains unclear whether other related drugs such as angiotensin receptor blockers (ARBs) can be effective in treating or preventing a crisis. Endothelin and other mediators of vascular disease are implicated in the pathogenesis of SRC, and thus interference with endothelin function by a specific inhibitor may offer a novel therapeutic approach. A vasodilating prostaglandin (prostacyclin) may also provide rapid control of blood pressure while improving renal blood flow. The overall outcome in SRC remains unsatisfactory in terms of acute disease outcome, morbidity, and the need for renal transplantation or long-term renal support with dialysis. Currently no evidence supports the prophylactic use of ACE inhibitors in patients with scleroderma who are at risk for SRC. Several studies have actually shown that use of an ACE inhibitor before the onset of SRC was associated with worse outcome, including higher mortality.[137,138,140]

Any newly developed hypertension in a patient with scleroderma should be urgently evaluated because the key to successful therapy is early detection and rapid intervention (Figure 84-15). Patients with SRC should be hospitalized and should immediately start taking an ACE inhibitor. Captopril, a rapid-acting ACE inhibitor, should be started to allow dose increases until systolic blood pressure is decreased by 20 mm Hg within 24 hours while avoiding hypotension. Treatment continues with an ACE inhibitor even if creatinine continues to rise. When full doses of an ACE inhibitor are not controlling blood pressure, other anti-hypertensive medications may be added, including calcium channel blockers, endothelin inhibitors, and

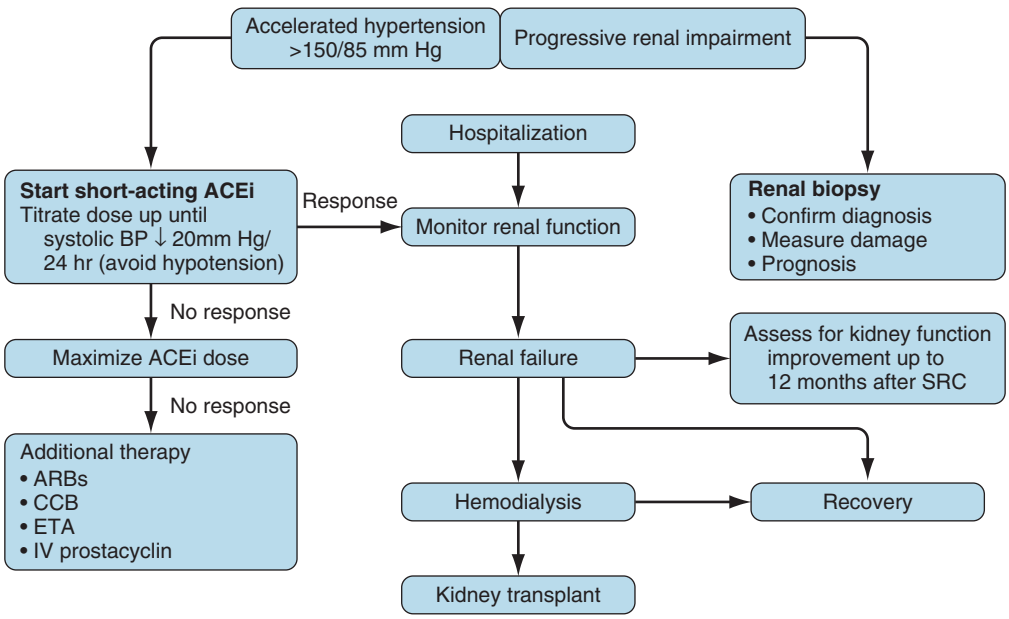

**Figure 84-15** Management of scleroderma renal crisis. ACEi, Angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; BP, blood pressure; CCB, calcium channel blocker; ETA, endothelin receptor antagonist; IV, intravenous; SRC, scleroderma renal crisis.

prostacyclin or an ARB. Some patients continue to have progressive renal failure despite attaining control of blood pressure. Other causes of renal disease always need to be considered, especially in patients with limited scleroderma and in those with a high level of proteinuria or abnormal urinalysis such as red blood cell casts. A renal biopsy should be performed to confirm the diagnosis and to gain insight into the prognosis by determining the degree of renal damage. Detection of other forms of glomerular inflammation via a kidney biopsy is important because it will dictate a different specific treatment approach.

Successful renal transplantation has been performed in patients with scleroderma, providing an overall survival benefit compared with long-term dialysis. Renal allograft survival at 3 years is about 60%, which is comparable with the rate observed in systemic lupus erythematosus. It is not recommended that renal transplantation be pursued until it is clear that recovery will not occur spontaneously. This determination can be made in part by assessing the degree of damage on renal biopsy and by waiting at least 6 months (some investigators suggest 2 years) after recovery from the acute crisis. Recurrence of SRC is uncommon (5%) after a renal transplant.

## Musculoskeletal Involvement

Musculoskeletal symptoms are almost always present in scleroderma, usually are multifactorial in origin, and often are the initial symptoms of the disease. The most common symptoms are nonspecific pain, stiffness, and diffuse muscular discomfort that mimics a flu-like syndrome. Impaired hand function, characterized by decreased hand mobility, reduced dexterity, and decreased grip force, is in particular a major source of difficulty in performing activities of daily living. The degree and type of musculoskeletal disease vary a great deal and are influenced by the duration of disease, the level of overall disease activity, and the subtype of skin involvement. For example, in early diffuse scleroderma, pain that is often widespread in areas of skin inflammation and advancing fibrosis can involve joint structures, tendons, subcutaneous tissue, and underlying muscle. In later stage diffuse disease, joint contractures and muscle atrophy are often associated with pain and loss of function, causing significant disability. In patients with limited scleroderma, puffy fingers and loss of hand function and grip may be the only musculoskeletal symptoms throughout the disease course. Although histologic evidence suggests that synovitis occurs, arthralgias, pain, and stiffness without signs of frank arthritis constitute the usual clinical picture. However, overlap syndromes of rheumatoid-like polyarthritis or inflammatory muscle disease can dominate the clinical picture in an individual patient.

In the early edematous phase of diffuse scleroderma, patients often are diagnosed with carpal tunnel syndrome as a result of soft tissue swelling and inflammation in the hand and wrist area. Erosive arthritis with joint space narrowing can be seen, but soft tissue swelling, periarticular osteopenia, and contractures of the joint are more common. Distal bone resorption, osteolysis, and periarticular calcinosis are found in the fingers of patients with later stage diffuse scleroderma. Contractures of the PIP and MCP joints are most common, and rarely, contractures of the distal interphalangeal joint occur. Patients with diffuse skin disease experience contractures of large joints, including wrists, elbows, shoulders, hips, knees, and ankles. These contractures are the hallmark of severe scleroderma and are associated with fibrosis and ankylosis of the joint, resulting from disease in the overlying skin, fascia, joint capsule, and tendons.

Tendon friction rubs can be felt as a coarse crepitus over joints or over the forearm or lower leg with adjacent joint movement. These rubs are thought to be a result of low-grade tenosynovitis, local edema, and fibrosis of the tendon sheath, fascia, and joint structures. Friction rubs are seen primarily in patients with diffuse skin disease; when present, they are an indicator of a poor overall prognosis. They are found in about 15% to 30% of patients and are more common in patients with diffuse skin disease and in patients with antitoposiomerase, anti-RNA polymerase, or anti-U3-RNP antibodies.[141]

In relatively small observational studies, the prevalence of signs of joint inflammation in scleroderma is estimated to be about two-thirds of patients.[142,143] A large multicenter survey reported the frequencies of synovitis, tendon friction rubs, and joint contractures to be 16%, 11%, and 31%, respectively.[144] Synovitis, tendon friction rubs, and joint contractures are more likely to occur together and are more prevalent in patients with the diffuse cutaneous subset. These manifestations also tend to be associated with severe vascular, muscular, renal, and interstitial lung involvement. Synovitis, joint contracture, and tendon friction rubs are associated with more severe disease and with systemic inflammation.

Erosive arthritis is commonly associated with periarticular calcinosis (Figure 84-16A) and can be seen with significant bone loss or osteolysis. A radiologic survey of 120 patients found abnormalities including erosion (21%), joint space narrowing (28%), arthritis (defined by concomitant erosion and joint space narrowing; 18%), radiologic demineralization (23%), acro-osteolysis (22%), flexion contracture (27%), and calcinosis (23%).[144] Radiologic studies using ultrasonography and MRI confirm that hand involvement is striking, with articular, bone, and soft tissue changes.[145,146] Resorption of distal phalanges was significantly associated with digital ulcers and extraarticular calcification; flexion contracture was associated with the diffuse cutaneous form and with high HAQ disability scores.[147] Calcinosis is most often seen in patients with digital ulcers but was similarly observed in patients with the diffuse or limited cutaneous subtype. Calcinosis is often seen in the subcutaneous tissue in areas of trauma such as the extensor surfaces of the forearms, elbows, or patellae. Unlike the more diffuse calcinosis seen in patients with myositis, calcium deposits in scleroderma tend to be found in clusters around joints and sites of trauma. These deposits can restrict joint motion and may be associated with acute inflammation similar to a gouty arthritis, or the deposits can rupture through the skin, weeping a thick, white material. Once the skin is broken, secondary infection can occur.

Erosive polyarthritis, seemingly specific for scleroderma, or seropositive rheumatoid arthritis can occur in patients with limited or diffuse skin disease. However, the prevalence of scleroderma with rheumatoid arthritis overlap is low (1% to 2%), with an estimated incidence of 5%.[144,148,149]

**Figure 84-16** **A**, Hands of a patient with scleroderma showing reabsorption of distal phalanges corresponding to radiographic evidence of (**B** and **C**) acro-osteolysis, calcinosis, and joint erosions.

This finding is confirmed by the low frequency of anti-citrullinated protein antibodies found in patients with scleroderma and arthritis. When an inflammatory arthritis is present, traditional medications used in rheumatoid arthritis can be helpful. One case series demonstrated that the TNF inhibitor etanercept appeared to be efficacious in improving active inflammatory joint disease in a subset of patients with scleroderma, and it was generally safe and well tolerated.

A sense of weakness in the muscles of the hands, arms, and legs is very common (80%) and can be subtle or profound. One study found measurable weakness in 30% of patients, with proximal more than distal strength being compromised. Myopathy in a person with scleroderma is often multifactorial, but patients with myopathy are at increased risk for poor outcome and decreased survival.[120] Weakness is often caused by muscle atrophy as a result of the inflexibility due to joint disease and fibrotic skin with lack of usual mobility and exercise. It also can occur because of malnutrition resulting from scleroderma-related bowel disease. Muscle weakness in scleroderma may be a result of direct muscle disease. In people with diffuse scleroderma, fibrosis can extend into the striated muscle, causing muscle atrophy and clinical weakness. This phenomenon has been called a *fibrosing myopathy*. It presents in the setting of severe diffuse skin disease with joint contractures and mild elevation of creatine phosphokinase (CPK). EMG demonstrates nonirritable myopathy, and a muscle biopsy shows little inflammation, fibrosis, and type 2 muscle atrophy. The fibrosing myopathy does not respond to traditional anti-inflammatory medications, including corticosteroids. This type of muscle disease is associated with cardiomyopathy, heart failure, and arrhythmia that can be severe and irreversible.[150]

Approximately 5% to 10% of patients with scleroderma have an inflammatory muscle disease that can follow the same course as polymyositis and other forms of idiopathic inflammatory myopathy. Patients present with rapid proximal muscle weakness associated with high CPK. EMG shows irritable myopathy, and muscle biopsy is typical of an inflammatory myositis. In cases with severe polymyositis, myocarditis can occur with heart failure. High levels of anti-PM/Scl-100 antibodies are found in about 4% of patients with SSc, often in association with acute inflammatory muscle disease. Patients with muscle weakness should be fully evaluated for underlying causes with the use of laboratory measures of muscle enzymes, EMG studies, MRI, and muscle biopsy. These studies will help differentiate inflammatory muscle disease from other forms of myopathy.

## Endocrine Involvement

Endocrine dysfunction can complicate the course and management of patients with scleroderma. The most common endocrine problem associated with scleroderma is thyroid disease, and the frequency of other endocrinopathies is similar to that of the general population. Thyroid disease is reported in 10% to 15% of patients with scleroderma.[151,152] A case-control study found a 10 to 14 times increased risk of hypothyroidism.[153] Evidence for both fibrosis of the thyroid and autoimmune injury exists. Patients with

features of the CREST syndrome are more likely to have hypothyroidism than are those with diffuse skin disease. An autoimmune basis for thyroid disease is suggested by one series, which found Hashimoto's thyroiditis in 6% and Graves' disease in 3% of patients.[154] In a survey of 719 patients with scleroderma, it was found that 273 (38%) had at least one other autoimmune condition; the most frequent was autoimmune thyroid disease.[155] Thyroid autoantibodies are commonly found in patients with scleroderma who have hypothyroidism. In addition, the association of CREST syndrome with autoimmune hypothyroidism and primary biliary cirrhosis has been reported, suggesting multiple autoimmune targets in these patients. Thyroid disease may not be recognized in patients who have subclinical disease or symptoms associated with chronic multisystem disease. It is recommended that thyroid function be monitored periodically, especially in patients with limited scleroderma who have CREST syndrome and in those with long-standing disease.

## Other Associated Manifestations

It must be recognized that several less common and often forgotten complications may require attention in patients who have scleroderma. Awareness of these associated problems can improve quality of life and prevent undue distress. Bone disease can occur for a variety of reasons. Most patients with scleroderma are women who are near or in menopause and therefore are at risk for osteoporosis and its complications. This risk is increased by the chronic inflammatory nature of the disease, disuse, and several commonly used medications, such as corticosteroids or proton pump inhibitors. Malabsorption and lack of sun exposure may lead to vitamin D deficiency, and bowel dysfunction can limit calcium intake. Avascular necrosis of carpal bones of the wrist is reported and is thought to be a result of scleroderma peripheral vascular disease. In addition, osteolysis or bony resorption of the tips or tufts of the fingers, middle phalanges, distal radius, and ulna bones (less commonly, the distal clavicle, ribs, mandible, and distal toes) may occur (Figure 84-16B and C). Acro-osteolysis is fairly common, presenting with shortening of the finger or pain of the fingertip. Osteolysis is thought to be a manifestation of peripheral vascular disease and poor nutritional blood flow on affected bones. Neurologic complications can be a significant unrecognized problem. The CNS is generally spared in scleroderma, but unilateral or bilateral trigeminal neuralgia is known to occur in a subset of patients. Peripheral neuropathy occurs in a higher percentage of patients than expected as a result of multiple causes, including nutritional deficiency from GI disease, entrapment neuropathy, vasculitis, or vasculopathy of small vessels typical of scleroderma vascular disease. Carpal tunnel syndrome can complicate diffuse scleroderma and may occur in patients with associated inflammatory joint disease.

Dry eyes (keratoconjunctivitis sicca) and/or mucous membranes (xerostomia) occur in about 25% of patients. Dry eyes may occur as the result of severe facial periorbital skin fibrosis, which inhibits full closure of the eyelids. Topical artificial tears should be used frequently in these cases. Facial changes alter oral aperture and decrease facial flexibility. Vertical lines around the lips and thinning of the lips along with pinching of the nose affect self-esteem, especially in younger women. A decreased oral aperture prevents daily oral hygiene and dental procedures from being performed easily. Loosening of the teeth happens because of loss of the normal periodontal ligament attaching the tooth to the alveolar bone. Decreased saliva and difficulty performing usual dental hygiene can lead to significant periodontal disease. Treatment of oral manifestations requires early referral for experienced dental care and frequent cleaning with fluoride treatment. Pilocarpine and cevimeline are agonists for the muscarinic cholinergic receptors that can increase saliva and improve symptoms of xerostomia.

Most data suggest normal fertility in scleroderma, but during pregnancy, risk for hypertension, SRC, or premature fetal loss is increased. Sexual performance is often affected, particularly in women with diffuse disease. Decreased sexual satisfaction is associated with painful inflexible joints, dry vaginal membranes, and general fatigue. Erectile dysfunction and associated impotence have been reported in more than 80% of men with scleroderma as a result of local fibrosis of the corporeal smooth muscle and scleroderma microvascular disease. Psychogenic and medication-induced sexual dysfunction must be considered.

Several causes of lower extremity lesions can occur, including skin fibrosis, stasis dermatitis, lipodermatosclerosis, panniculitis, subcutaneous calcinosis, and leg ulcers. Leg ulcers may result from traumatic breakdown of atrophic fibrotic skin, ischemic ulcers as a result of scleroderma vascular disease, vasculitis, and occlusive vascular events resulting from an associated hypercoagulable state. Livedoid vasculopathy is a rare complication causing skin ulcerations on the lower leg and foot as the result of small vessel vasculitis or small vessel thrombosis.

## Psychosocial Aspects

Scleroderma is a disease that can alter virtually every aspect of the patient's life. Although scleroderma is often mild in its expression, the patient is now faced with a life crisis and must deal with a rare chronic disease that is complex and not completely understood by the medical community. Patients learn that scleroderma is potentially a life-threatening disease that alters physical capacity and can be disfiguring. At the onset of the disease, patients are often confused, anxious, and frightened. Fear and misunderstanding become a major source of distress. Studies of psychosocial adjustment support the conclusion that a substantial proportion of patients with scleroderma have difficulty adapting to the disease and have reduced quality of life measures. Although little evidence suggests that scleroderma directly affects the CNS with a direct organic cause for altered mental status, a complex array of medications used to treat the disease and its complications may have some influence on mood and the sense of well-being.

Psychosocial aspects of the disease do not appear to be consistently influenced by age, gender, ethnicity, education, or marital status. However, some data suggest that being disabled with low financial income leads to higher psychological distress. Evidence suggests that depression in patients with scleroderma is common and is related more to the patient's personality, degree of pain, and level of social

support than to actual disease severity. Disease-related disability, as measured by the HAQ-DI, is a more important predictor of adjustment problems than are disease symptoms related to severity. Pain and fatigue are common in scleroderma. Together with depressive symptoms, they are the most significant determinants of physical functioning and social adjustment—two important components of health-related quality of life—in patients with limited and diffuse disease subtypes.

Personality traits influence the degree of psychological adjustment. Patients with scleroderma who describe themselves as anxious, worried, tense, or detail-oriented are more likely to be depressed than are patients who describe themselves as agreeable or extraverted and outgoing. Disease unpredictability and lack of control cause increased distress. High self-reported uncertainty is related to poor adjustment. Thus, increasing the patient's understanding of the disease and expectations through education may reduce uncertainty and improve quality of life. Body image dissatisfaction is a significant concern. Patients are distressed by disease-related changes in visible parts of their body, especially the fingers and hands. A survey found that tight skin and facial changes were not as distressful as hand deformity with finger contractions and hand dysfunction. Sexual function is affected in both men and women with scleroderma. A significant proportion of men experience erectile dysfunction. Women with scleroderma, particularly those with diffuse skin disease, have high levels of sexual impairment compared with women who have other chronic diseases for which sexual function has received greater attention. Both women with scleroderma and women with other chronic diseases may have a decreased sexual drive during the disease course. The impact of sexual function on quality of life is not well studied, but it exists and should be appropriately addressed as part of comprehensive care.

Psychological factors with demonstrated relevance to scleroderma include pain, depression, and distress about disfigurement, physical function, and social function. Although these dimensions of quality of life are interrelated, pain, depression, and distress about disfigurement are common and may respond to psychological intervention. Such intervention begins with providing compassionate support beyond just ordering medications. It is important to spend time in a comfortable setting educating patients about scleroderma, providing a clear understanding of the degree of their disease, and explaining to them what they need to do and what can be done for relief. Having insight into social support and life circumstances, including financial distress, work environment, and family structure, provides a framework for helping to decrease external distress. For example, a family conference held to explain the reality of the health situation or the needs of the patient can reduce home tension and can clarify the patient's capacity in their family role. An adjustment in the work environment (e.g., permission to use a space heater) can make a difference. Clearly, effective social support improves quality of life. Follow-up visits that provide time to discuss issues of coping and social support are most important. Recognizing the personality of patients while addressing their specific concepts is helpful. Treating underlying depression and especially providing effective management of disease-related pain help to improve quality of life and reduce social and psychological distress. Body image dissatisfaction is a significant concern in women with scleroderma and should be assessed routinely. Early identification and treatment of body image dissatisfaction may help to prevent depression and psychosocial impairment in this population. The possibility of premature death from the disease is a major cause of fear and needs to be addressed with the patient and the family. Most often, life expectancy is not influenced by the disease, yet patients fear death because they have scleroderma. When a patient is facing death from severe disease, appropriate honest and sensitive support must be provided.

## TREATMENT

### Immunotherapy

Scleroderma is thought to be an inflammatory connective tissue disorder triggered by an autoimmune process.[87] Nonselective immunosuppressive treatments are usually used in scleroderma to treat specific organ manifestations such as early progressing skin disease, active ILD, and underlying inflammatory joint or muscle disease (Table 84-6). CYC has shown some modest efficacy in scleroderma-related ILD in a randomized placebo-controlled trial.[87] Current therapeutic protocols use CYC as a daily oral regimen or as monthly IV therapy until control of disease is achieved. The CYC is often followed by maintenance treatment with AZA or MMF, agents that have anti-proliferative effects on inflammatory cells and in particular on activated T and B lymphocytes.[156] Uncontrolled studies suggest benefit of MMF in both ILD and active scleroderma skin disease.[157-160] Most physicians are now using MMF as the preferred first agent for ILD and skin disease because of its potential benefit and safer profile compared with CYC. Evidence supporting the use of AZA as a primary agent to treat scleroderma-related ILD is weak and remains limited to small retrospective studies. Two open-label trials support its role as maintenance therapy after primary CYC immunosuppression.[161-163]

Methotrexate (MTX) is frequently used in patients with scleroderma to treat associated inflammatory arthritis and myositis. MTX efficacy in treating skin disease and lung function was investigated in two randomized placebo-controlled trials and showed only a small benefit on skin scores after 6 months (with weekly intramuscular injections) or after 12 months (with weekly oral therapy), respectively.[164,165] Based on the findings of these studies, many experts use MTX for active skin disease. However, other experts prefer using MMF as an initial agent for active skin disease because uncontrolled studies have shown greater benefit.

Selective immunotherapy has also been used in scleroderma (see Table 84-5). T lymphocyte–directed treatments such as cyclosporin A, sirolimus (rapamycin), and antithymocyte globulin have shown some benefit.[166,167] However, these studies generally were small and were limited by drug toxicity. The use of extracorporeal photoimmunotherapy or photopheresis has been reported with modest improvement in skin disease but lack of any efficacy on internal organ manifestations.[168] This approach is not currently supported. Preliminary studies of rituximab, a chimeric IgG1 monoclonal antibody directed against CD20, a surface molecule

HSCT, Hematopoietic stem cell transplantation; IVIG, intravenous immunoglobulin; TGF-β, transforming growth factor-β.

expressed on early pre-B and mature B cells, have shown some promising results, with improvement of skin fibrosis and stabilization of lung function.[169-172] This clinical benefit awaits confirmation in larger, controlled trials. Administration of IV immunoglobulin (IVIG) to patients with scleroderma has been reported in small open-label studies with some evidence that it can improve skin fibrosis or joint disease.[173,174]

Studies of cell-based immunotherapy using autologous hematopoietic stem cell transplantation (HSCT) preceded by myeloablative or nonmyeloablative conditioning regimens have recently been completed.[52,53] In the Autologous Stem Cell Transplantation International Scleroderma (ASTIS) trial and the American Scleroderma Stem Cell versus Immune Suppression Trial (ASSIST), patients with scleroderma were randomized to receive HSCT or pulsed IV doses of CYC administered monthly. Overall, these investigations have confirmed previous observations that HSCT is effective in rapidly controlling skin disease, stabilizing lung function, and improving quality of life as assessed by patient-reported outcome measures.[175-177] HSCT also shows a better long-term event-free and overall survival compared with CYC. Despite these positive results, the high treatment-related morbidity and mortality (10.1% in ASTIS) associated with high-dose immunosuppression and the evidence that the disease tends to relapse in a substantial subset of treated patient, are still preventing consideration of this approach as standard of care for patients with scleroderma. Stratification of subjects based on disease severity and selection of appropriate candidates remain crucial for a safe and effective use of HSCT. Nonmyeloablative (immunoablative) conditioning regimens without HSCT have demonstrated similar results.[178]

## Treatment of Fibrosis

To date, no drugs have proved able to reverse the fibrotic disease process in scleroderma, but several potential agents are being used off-label or are under investigation. Their use is still based on in vitro data, animal studies, or case series because formal well-designed controlled trials are still missing.

D-Penicillamine is a chelating agent that blocks collagen cross-linking and thus has the potential to exert antifibrotic effects. Several case reports and retrospective reviews have suggested that D-penicillamine is beneficial.[179] A double-blind, randomized clinical trial comparing the efficacy of low-dose versus high-dose D-penicillamine in early diffuse scleroderma found no significant difference between skin scores of the two groups at 24 months.[180] Given the potential toxicity of D-penicillamine, its lack of effectiveness in the only controlled trial, and the long duration before benefit was achieved in several uncontrolled surveys, the drug has fallen out of favor and generally is not used.

Transforming growth factor (TGF)-β is a cytokine known to promote fibroblast proliferation and differentiation, in addition to upregulation of collagen and extra-cellular matrix synthesis. Therefore, it represents an appealing target to specifically control progression of collagen and extra-cellular deposition in tissues. A human recombinant neutralizing TGF-β antibody was studied compared with placebo in a relatively small phase I/II trial in patients with early diffuse scleroderma.[181] No clinical benefit was observed when skin score or lung function testing parameters were evaluated. Although the results of this study were negative, it does not negate the idea that a more potent neutralizing antibody might be helpful. A new study is ongoing.

Imatinib, dasatinib, and nilotinib are small molecules that inhibit the tyrosine kinase activity of the abl-kinases and platelet-derived growth factor receptors, thus

interfering with important profibrotic pathways activated in scleroderma. In addition, dasatinib inhibits Src kinases, which are also involved in fibroblast differentiation and secretory function.[182] Several small uncontrolled trials with tyrosine kinase inhibitors have been reported with no indication of benefit and frequent adverse events including fluid retention, nausea, fatigue, and elevation of creatine kinase.[183,184] Therefore, although a potent antifibrotic effect has been shown by tyrosine kinase inhibitors in vitro or in animal models, clinical studies to date have not provided solid evidence for their use in treating skin and systemic fibrosis.

Halofuginone, a plant-derived alkaloid with antifibrotic properties via inhibition of TGF-β and T cell activation, is known to reduce collagen production in animal models. Only limited use of topical halofuginone therapy in patients with scleroderma skin disease is reported, with some encouraging results.[185] Rosiglitazone is an agonist of peroxisome proliferative-activator receptor-γ and has been shown to suppress in vitro fibroblast production of collagen and to alleviate fibrosis in the bleomycin-induced scleroderma mouse model.[186] Pirfenidone (5-methyl-1-phenylpyridin-2[1H]-one) is a novel agent with antifibrotic and antiinflammatory properties. In a phase III randomized controlled trial, compared with placebo, pirfenidone has shown significant benefit (decreased disease progression) and a relatively mild adverse-effect profile in patients with idiopathic pulmonary fibrosis.[187] A clinical trial is ongoing in scleroderma-related ILD. Neutralizing antibodies against connective tissue growth factor (CTGF) can effectively suppress the development of skin fibrosis in animal models, and anti-CTGF therapy is now under consideration to treat scleroderma.[188]

New understanding of molecular pathways that play a unique role in fibrosis is emerging that may provide new targets for treatment. This understanding includes insight into fibroblast-myofibroblast differentiation, epithelial-mesenchymal transition, and fibroblast interactions with extra-cellular matrix via cellular integrins.

### Treatment of Vascular Disease

Although scleroderma is generally considered a fibrosing disorder, it is well recognized that underlying vasculopathy plays a fundamental role in its pathogenesis and associated tissue injury. In RP, small and medium-sized peripheral blood vessels involved in tissue nutrition and body thermoregulation are affected. The pathologic and clinical consequences of scleroderma vascular disease are not limited to the skin but are widespread and are found in all involved organs. Currently, no guidelines have been put forth for a general treatment of scleroderma vascular disease. Therefore, pharmacologic therapies are focused on the treatment of organ-specific disease such as scleroderma renal crisis, PAH, and RP (see related sections). Although conventional treatment strategies with nonspecific vasodilator agents are still routinely used, novel agents targeting specific biologic processes involved in scleroderma vascular disease (i.e., prostacyclin, endothelin antagonists, statins, and phosphodiesterase inhibitors) are now available with evidence of broader beneficial effects (see the sections on Raynaud's Phenomenon and Pulmonary Hypertension).

## SUMMARY OF CURRENT PRACTICAL RECOMMENDATIONS FOR TREATMENT

The key to current management of scleroderma is to not isolate treatment to one problem that seems to be dominant but to appreciate the complexity and dynamics of this multisystem disease (Table 84-7). It is clear that use of just one drug is not effective in managing scleroderma and that long-term therapy is required with possible adjustments based on specific clinical circumstances. A combination therapy approach that attempts to treat the immune response, the vascular disease, and the underlying tissue fibrosis is recommended.

Patients with severe RP should be taking vasodilators and anti-platelet therapy with aspirin. Vasodilator treatment should start with a calcium channel blocker, with a

**TABLE 84-7** Current Recommendations for Treatment of Scleroderma

| Manifestation | Primary Therapy | Alternative/ Second-Line Therapy |
|---|---|---|
| Raynaud's phenomenon | Vasodilators (CCB or PDE5 inhibitors)<br>Anti-platelet | PDE5 inhibitors, prostacyclin, endothelin antagonists |
| Hypertensive renal disease | ACE inhibitors | ARBs, CCB, prostacyclin, renal transplant (wait at least 24 mo) |
| GI involvement | **Upper GI**<br>Dental/periodontal care, lifestyle modifications, proton pump inhibitors, prokinetics<br>**Lower GI**<br>Probiotics, rotational antibiotics | EGD to treat stenosis and/or GAVE<br><br>Total parenteral nutrition |
| Skin | Mycophenolate mofetil, cyclophosphamide | IVIG, ATG, research trial (severe cases) |
| Interstitial lung disease | Mycophenolate mofetil, cyclophosphamide | Research trial |
| Pulmonary arterial hypertension | PDE5 inhibitors, endothelin antagonists, prostacyclin, soluble guanylate-cyclase stimulators | Combination therapy, atrioseptostomy, lung transplant, research trial |
| Cardiac involvement | Heart failure therapy, diuretics, CCB | Immunosuppression (myocardial inflammation) |
| Joints | Prednisone, methotrexate, TNF inhibitors | IVIG (if contractures and rubs are present), PT/OT |
| Muscles | Prednisone, methotrexate, azathioprine | IVIG |
| Psychosocial | Anti-depressants, pain control, sleep control | Support group |

ACE, Angiotensin-converting enzyme; ARBs, angiotensin receptor blockers; ATG, anti-thymocyte globulin; CCB, calcium channel blockers; EGD, esophagogastroduodenoscopy; GAVE, gastric antral vascular ectasia; GI, gastrointestinal; HSCT, hematopoietic stem cell transplantation; IVIG, intravenous immunoglobulin; PDE5, phosphodiesterase-5 inhibitor; PT/OT, physical therapy/occupational therapy.

second agent added if needed—this can be a phosphodiesterase inhibitor or intermittent IV prostacyclin (it is hoped that oral prostacyclin will be available soon). If digital ulcers are recurring, then the addition of an endothelin inhibitor or a statin may be indicated.

Patients with hypertensive renal disease should be treated urgently with an ACE inhibitor or, if needed, with additional ARBs or anti-hypertensive agents, including calcium channel blockers or a prostacyclin analogue. The use of ACE inhibitors to prevent a scleroderma renal crisis is not recommended.

All patients need periodic professional dental care, and if loss of saliva production is noted, the use of pilocarpine or cevimeline is recommended. Patients with upper GI disease should be treated with lifestyle changes, such as improving their eating habits; with proton pump inhibitors; and in cases of unremitting symptoms, with prokinetic drugs (e.g., metoclopramide and domperidone). If the lower intestinal tract is involved, then rotating antibiotics can improve episodes of pseudo-obstruction, diarrhea, or malabsorption.

Management of established, nonactive cutaneous involvement is based on supportive care with use of moisturizing agents to prevent excessive dryness. First-line therapy for active skin disease has not yet been formally established, but immunosuppressive therapy is recommended based on severity and level of disease activity. MMF is preferred by many clinicians for mild to moderate disease, although some persons still recommend MTX. Combination with IVIG or cyclophosphamide alone (daily oral doses or monthly IV administration) should be considered for severe, aggressive disease. More innovative and targeted therapies are needed. These therapies may include immune cell depleting protocols (i.e., rituximab and anti-thymocyte globulin) or biologic agents (i.e., tocilizumab, abatacept, and belimumab), which are currently under evaluation. Immunoablation or myeloablation with or without hematopoietic stem cell rescue may be an option in selected patients who are not responsive to conventional treatment. Participation of patients in new clinical trials should be pursued.

Active ILD should be treated with immunosuppression. MMF is now commonly used as initial therapy. CYC (daily oral or monthly IV) also can be used as a first-line agent, but its use should be limited to 6 to 12 months, followed by maintenance (several years) with a secondary immunosuppressive drug (i.e., MMF or AZA). High-dose immunosuppression (HSCT) or novel therapies (e.g., tocilizumab and rituximab) should be considered in refractory cases. Lung transplant is a viable option for patients with end-stage lung disease.

Pulmonary vascular disease and PAH are best treated with vasoactive drugs, including endothelin-1 inhibitors, phosphodiesterase inhibitors, prostacyclin analogues, or soluble guanylate-cyclase stimulators given alone or in combination. The role of anticoagulation or immunosuppressive agents is not yet defined. Treatment of associated heart failure is most important.

Cardiac disease should be treated with vasoactive drugs such as calcium channel blockers, other anti-hypertensive agents, diuretics, and antiarrhythmic medications. Immunosuppression should be used if inflammatory muscle or pericardial disease is present.

Distinct manifestations of inflammatory arthritis should be treated in a similar fashion to the therapeutic approach used in rheumatoid arthritis. However, a fibrosing process causing a nonerosive arthropathy in association with friction rubs and joint contractures is best treated with the same medications used for active scleroderma skin disease.

Treatment for muscle disease will vary depending on the presence of inflammatory myositis or a nonirritable fibrosing myopathy. The former is treated with corticosteroids, MTX, or other immunosuppressive agents effective for immune-mediated polymyositis. The fibrosing muscular process is best treated with the same approach used for scleroderma skin disease.

All patients need emotional and physical support. Scleroderma is a painful disease, and managing pain is essential for reducing depression and improving quality of life. Managing pain may require the use of sleep aids (e.g., lorazepam or zolpidem) and/or intermittent use of narcotics. Physical and occupational therapy is most important early in the course of the disease to reduce pain and improve activities of daily living. Family counseling helps the patient cope by providing a clear understanding of what is needed at home. Adjustment of the work environment (e.g., limiting time at work, adjusting room temperature, and changing work assignments) or helping patients obtain disability support is also important. Open communication between the physician and the patient provides an essential element of care.

CHAPTER 85

# Inflammatory Diseases of Muscle and Other Myopathies

Kanneboyina Nagaraju • Heather S. Gladue • Ingrid E. Lundberg

**KEY POINTS**

- Myopathies are a heterogeneous group of muscle diseases characterized by symmetric proximal muscle weakness and frequent involvement of other organs.
- Myopathies are often accompanied by elevated levels of serum muscle enzymes and abnormal electromyograms.
- Histology shows varying degrees of inflammation and muscle fiber degeneration and regeneration.
- Some patients have autoantibodies that bind to molecules involved in protein synthesis, and these antibodies are often associated with distinct clinical phenotypes.
- Corticosteroids and cytotoxic drugs are common therapies for inflammatory muscle disease.

Inflammatory muscle diseases are a heterogeneous group of systemic autoimmune rheumatic disorders characterized by chronic muscle weakness, muscle fatigue, and mononuclear cell infiltration into skeletal muscle. These disorders were described in the literature more than a century ago as generalized muscle disorders affecting principally the trunk and proximal limb muscles, with or without skin involvement.[1-5] It was also recognized that these diseases can range from acute and even fatal to slow, progressive, chronic, insidious conditions, with patterns of relapse and remission. Steiner's[6] summary of myositis cases in 1903 made a clear distinction between idiopathic polymyositis (PM) and other forms of myositis caused by bacteria and parasites,[6] and Stertz[7] in 1916 first reported an association between dermatomyositis (DM) and internal malignancy.[7] At about the same time, Batten[8] described the first case of DM with classic histologic features in a child.

Since the 1940s, it has been recognized that PM may occur in the absence of cutaneous lesions, muscle pain, or constitutional symptoms. It may present in an acute, subacute, or chronic insidious form, with some fraction of cases showing systemic features or involvement of organs and tissues.[9] The differential diagnosis has been described independently by several investigators, and the most chronic form was differentiated from an adult variety of muscular dystrophy.[10-12] Banker and Victor[13] noted that DM in children was different and involved a greater degree of vascular inflammation and thrombosis (systemic angiopathy). The first, and still widely used, classification scheme and set of diagnostic criteria for myositis were proposed by Bohan and Peter in 1975.[14,15] They include PM and DM but not the later described subset known as inclusion body myositis (IBM). IBM was later defined by the presence of distinct histopathologic changes, including vacuoles and nuclear and cytoplasmic inclusions, as well as by distinct clinical features, including resistance to glucocorticoids.[16,17]

## EPIDEMIOLOGY

The actual annual incidence of inflammatory myopathy is currently unknown. Because these diseases are so rare, no large-scale epidemiologic studies have been reported. However, several retrospective studies have reported an annual incidence of less than 10 per million individuals[18-22] (Table 85-1). This number may be an overestimate, given that the Peter and Bohan diagnostic criteria used in these studies did not distinguish IBM as a separate disease entity. The prevalence of IBM has been estimated to be 10.7 per million in the United States, 9.3 per million in Australia, and 4.9 per million in the Netherlands.[23-25] The age-adjusted prevalence of IBM for those older than 50 years was reported as 16 to 35 per million.[24,25] In some geographic areas, IBM appears to be the most common acquired progressive myopathy, representing 16% to 28% of all inflammatory myopathies.[25] However, there may be referral biases in these studies. The incidence-prevalence studies need to be interpreted cautiously, given that most have not reported confidence intervals for their rates.

The incidence of the various myopathies varies according to ethnicity, age, and gender. Some studies have reported that the incidence of PM is higher in black patients than in white patients.[18] Idiopathic inflammatory myopathies (IIMs) can occur in any age group, from early childhood to late in adult life. The onset of PM is usually in the late teens or older: the mean patient age at onset is 50 to 60 years. DM shows two peaks: 5 to 15 years and 45 to 65 years. IBM is commonly seen in individuals older than 50 years and is rare in younger adults. Some studies have reported gender-specific incidence rates. For example, in the case of PM and DM, females are more commonly affected than males (ratio >2:1), whereas in IBM, the converse is true (again, >2:1 ratio).

Inflammatory myopathies can occur in association with other autoimmune connective tissue diseases such as scleroderma, systemic lupus erythematosus (SLE), rheumatoid arthritis, Sjögren's syndrome, mixed connective tissue disease, polyarteritis nodosa, and sarcoidosis. Significant proportions of all myositis patients (11% to 40%) have an associated connective tissue disease.[23,26,27] Several studies have also confirmed an association between malignancies and inflammatory myopathies. A 2-decade-long retrospective study of myositis patients revealed that myositis in

**TABLE 85-1** Incidence of Inflammatory Myopathies

| Country | Study Dates | Incidence (million/yr) | Reference |
|---|---|---|---|
| United States | 1963-1982 | 5.5 | 18 |
| United States | 1947-1968 | 5.0 | 20 |
| Australia | 1989-1991 | 7.4 | 21 |
| Sweden | 1984-1993 | 7.6 | 22 |
| Israel | 1960-1976 | 2.1 | 246 |

approximately 12% (37/309) of the patients was associated with malignant disease. A majority (81%) (30/37) of the patients studied had DM, and the remainder (19%) had PM. Overall, the frequency of malignancies has varied widely (4% to 42%) in different studies,[19,28] but in general, the incidence of malignancy is higher in DM patients than in IBM or PM patients.[29] It is difficult to determine the relative risks for a particular malignancy because a variety of malignancies are associated with myositis, and only small numbers of individual malignancies have been reported in any one study.

## ETIOLOGY OF MYOSITIS

### Genetic Risk Factors

An association with immune response genes and occasional reports of familial clustering of myositis support the role of genetic factors in these diseases.[30-35] Polymorphisms in class I and II human leukocyte antigen (HLA) genes are known genetic risk factors for several autoimmune diseases that include myositis, but the mechanisms for these associations remain unclear. One possibility is that because the gene products influence T cell repertoire development, tolerance, and immune responses to foreign agents, certain polymorphisms are selected on the basis of environmental triggers. It appears that haplotypes HLA-DRB1*0301 and HLA-DQA1*0501 are the strongest known genetic risk factors for all forms of myositis in whites. However, different phenotypes have additional HLA risk and protective factors.[35,36] In African-American patients neither DRB1*0301 nor DQA1*0501 is strongly associated with myositis. Instead, the HLA-DRB1*08 allele shows the highest general risk for myositis, whereas the HLA-DRB1*14 allele is strongly protective in African-American patients. The HLA-B8/DR3/DR52/DQ2 haplotype is found in a significant proportion of IBM patients.[37] The risk and protection conferred by HLA associations differ significantly among different ethnic and serologic groups. For example, in some populations (e.g., Koreans, Mesoamericans), there is no association with HLA genes.[33] Further, HLA-DRB1*0301, which is a risk factor in whites, is a protective factor in the Japanese population.[38] The HLA-DRB1*0301, HLA-DQA1*0501, and HLA-DQB1*0201 alleles are strongly associated with myositis-specific antibodies in PM patients.[39] Mechanistic data supporting the role of HLA molecules in disease pathogenesis are, unfortunately, lacking at present. Some studies reported that maternally derived chimeric cells are present in the peripheral blood and muscle tissues of juvenile DM patients, suggesting that HLA alleles control the occurrence of chimerism and explain the HLA association found in these disorders.[40,41] Like other autoimmune disease conditions, myositis is a complex multigenic disorder involving other non-HLA immune response genes (e.g., cytokines and receptors, including TNF, IL-1, and TNFR-1); complement components (e.g., C4, C2); immunoglobulin (Ig) heavy-chain allotypes; and T cell receptors.[42] Polymorphisms in some non-HLA genes, such as signal transducer and activator of transcription 4 gene (STAT4) and C8orf13–BLK, appear to contribute prominently in Asian populations.[43,44] The exact contribution of the genetic component in these disorders is currently unknown, in part because of their rarity, the small number of subjects in any single cohort, and the heterogeneity seen in the disease phenotype. A recent genome-wide association study (GWAS) of DM patients (adult and juvenile) has confirmed the MHC as the major genetic region associated with DM. Furthermore, DM also shares non-MHC genetic features with other autoimmune diseases, suggesting the presence of additional novel risk loci.[45] International collaborative efforts are currently under way to identify novel genetic and environmental risk factors in myositis.

### Environmental Risk Factors

The temporal association of myositis onset and environmental agents in certain individuals suggests that specific exposures in the context of certain genetic backgrounds can initiate muscle inflammation. Common environmental agents implicated in myositis include infectious organisms, such as viruses and bacteria, and noninfectious agents, such as drugs and food supplements (Table 85-2). For example, enteroviruses (influenza, coxsackievirus, echoviruses) and retroviruses (human T-lymphotropic virus-I) are known to induce muscle inflammation. The myositis associated with enteroviruses usually occurs in children and is generally self-limited. A viral cause is strengthened by the presence of high-titer anti-viral antibodies and viral particles in patients' serum and tissue samples,[46,47] as well as the induction of muscle inflammation by enteroviruses in animal models. A more recent association was observed between a previous cytomegalovirus (CMV) infection and a subphenotype of PM and DM patients with high frequency of so-called *CD28-null T cells* (see later), indicating that some viral infections may influence the immune system and lead to chronic inflammation.[48] Similarly, some microorganisms, such as staphylococci, clostridia, and mycobacteria, are known to affect skeletal muscle and cause acute muscle inflammation, but there is no evidence that these organisms actually cause chronic, self-sustaining muscle inflammation.

Parasites such as *Toxoplasma gondii*, *Trypanosoma cruzi*, and *Borrelia burgdorferi* have been implicated in the triggering of IIMs. The evidence in support of a parasitic cause includes the recovery of parasites from some myositis patients and their serologic response to the parasites; improvement in myositis symptoms after treatment with anti-parasitic drugs; a histologic picture of inflammation, including infiltration of macrophages and CD4 T cells; and induction of myositis after parasitic infection in animal models.[49-55]

Ultraviolet (UV) light irradiation is likely to be a risk factor for DM because epidemiologic data have

demonstrated a latitude gradient of PM and DM, with the latter more frequent closer to the equator and the former more frequent in northern countries. The ratio between PM and DM is associated with a latitude gradient and is directly correlated with UV light irradiation. This observed correlation is particularly strong in a subset of DM patients with anti–Mi-2 autoantibodies, indicating that UV light may be an environmental risk factor for its development. The association between UV light exposure and the subtype of myositis suggests that UV light is an exogenous modifier that can influence the clinical and serological phenotype in myositis.[56,57]

Smoking is a risk factor for a subtype of myositis, the anti-Jo-1 positive, (one of the anti-synthetase syndromes—see the section on autoantibodies) and has a possible interaction with the HLA-DRB1*03 genotype.[58] Environmental and occupational agents such as dusts, gases, or fumes are also reported risk factors for patients with anti-synthetase syndrome.[59] These inhaled risk factors together with the high frequency of interstitial lung disease (ILD) as a manifestation of the anti-synthetase syndromes indicate a role for the lung as target of the immune reaction in this subset of myositis.

Malignancy is an additional risk factor for myositis, and there is a strong association between DM and malignancies. This early clinical observation has been confirmed in epidemiologic studies.[28,60] With regard to PM and IBM, the association with malignancy is less convincing. The increased risk of malignancy associated with DM has been established both at the time of DM diagnosis and more than 10 years after diagnosis. A subgroup of DM has been named *cancer-associated dermatomyositis* (CADM). *CADM* is often used to classify patients with DM with a detected cancer within 3 years before or after DM diagnosis, although the time span between the malignancy and DM varies between studies. No specific malignancy is associated with DM; rather, the most frequent malignancies are also the most common malignancies in the population.

The pathophysiologic mechanism for the association between malignancy and DM has not been clarified, but there could be several explanations. The strong association between malignancy and the onset of DM, the observation that removal of a tumor sometimes results in amelioration of muscle weakness, and the fact that tumor reappearance sometimes coincides with muscle weakness, suggests that DM could be a paramalignant phenomenon. That is, the development of myositis is a consequence of the malignancy (related to autoantigens), or the malignancy and DM share disease mechanisms. The molecular mechanisms underlying this unique association are currently unclear, however. A recent report has shed some light on the connection between DM and malignancy by showing that myositis-specific antigens are highly expressed in cancer tissues, as well as in regenerating muscle cells of myositis patients.[61,62] It has been proposed that in cancer-associated myositis, an autoimmune response directed against cancer cross-reacts with regenerating muscle cells, enabling a feed-forward loop of tissue damage and antigen selection.[63] This is further supported by the association between CADM and two newly identified myositis-specific autoantibodies (TIF1-γ and NXP2) in adult patients, (see the paragraph on myositis autoantibodies). For malignancies that develop during established disease, the potential explanations include the presence of chronic inflammation or prolonged immunosuppressive treatment, which could contribute to the development of malignancy.

A recent report notes a novel association of myositis with hypertension, diabetes, and ischemic heart disease. The prevalence of hypertension and diabetes in this population was 62% and 29%, respectively, considerably higher than the background prevalence of 9.4% and 4%. The authors of this report suggest that hypertension and ischemic heart disease are more likely to be present before the diagnosis of myositis, whereas hypertension and diabetes occur more frequently following the diagnosis of myositis in patients with DM than in patients with PM or IBM, suggesting that it is essential for the physician to perform a comprehensive assessment of vascular risk factors in these patients.[64] The same group also reported that patients with IIM are at a 75% increased risk for mortality, and cardiovascular diseases followed by infection and malignancy account for the most common causes of death.[65]

## Mimics of Myositis

A variety of factors induce the clinical and pathologic spectrum that mimics myositis in some individuals (see Table

85-2). A number of drugs are known to cause a myopathy that closely mimics myositis. For example, D-penicillamine causes clinically and histologically indistinguishable IIM.[67] Likewise, commonly used lipid-lowering drugs such as statins (e.g., atorvastatin, lovastatin) can cause a myopathy that resembles inflammatory myositis. These agents inhibit 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase, a rate-limiting enzyme involved in the conversion of HMG-CoA to mevalonic acid, thereby preventing the synthesis of bioactive sterol and nonsterol metabolic intermediates in the cholesterol synthetic pathway. The mechanism by which these drugs cause myopathy is not yet clear.[68-70] Patients with anti-HMGCR antibodies often have prominent myofiber necrosis with little or no muscle inflammation, also referred to as *necrotizing autoimmune myopathy* (NAM). It has been suggested that statins upregulate HMG-CoA autoantigen in regenerating muscle cells that, in turn, sustain an autoimmune response even after statin withdrawal, providing a mechanism for statin-induced immune-mediated necrotizing myopathy.[71] However, recent studies have indicated that the majority of NAM patients are statin-naïve, and anti-HMGR antibody titers correlate with muscle strength, suggesting a pathogenic role for these antibodies in NAM[72] (see details in Necrotizing Myopathies). Other drugs, such as hydroxyurea, can cause skin rashes that resemble DM.[73] TNF inhibitors have been associated with the onset of autoimmune diseases such as vasculitis and a lupus-like syndrome. Recent reports have suggested that TNF inhibitors in inflammatory arthritis patients either induce or exacerbate DM or anti-Jo-1-positive PM.[74,75,79,80] Some other reports have pointed to the vaccine adjuvant aluminum hydroxide as a cause of macrophagic myofasciitis. Histologic examination shows infiltration by macrophages and some $CD8^+$ T cells into the endomysium, perimysium, and epimysium, together with clinically elevated creatine kinase (CK) levels, muscle weakness, myalgias, fatigue, and arthralgias.[76] Despite some reports of vaccine-induced myositis, systematic investigation has failed to link any vaccine to myositis.[77]

## PATHOGENESIS

Significant advances have been made in our understanding of the pathogenesis of the human inflammatory myopathies.[78-83] It is generally thought that IIMs are autoimmune in origin because they are frequently associated with other autoimmune diseases (e.g., Hashimoto's thyroiditis) and collagen vascular diseases (e.g., scleroderma). Many patients exhibit an autoantibody response, including the presence of myositis-specific autoantibodies; some studies have provided evidence for lymphocyte-mediated muscle fiber injury, and a favorable response to immunosuppressive therapies in some patients supports an autoimmune cause of these disorders.

### Humoral Immune Response

More than 50% of all IIM patients have uniquely defined autoantibodies, some of which are specific to myositis, and some of which are merely associated with myositis. These are generally referred to as *myositis-specific autoantibodies* (MSAs) and *myositis-associated autoantibodies* (MAAs), respectively. MAAs include autoantibodies to various nuclear and cytoplasmic antigens. Anti-nuclear antibodies (ANAs) present in myositis are not particularly associated with any disease subgroup, whereas MSAs that are directed against antigens of the protein synthesis pathway (e.g., aminoacyl–transfer RNA [tRNA] synthetases and signal recognition particles) and nuclear components (e.g., nuclear helicase [Mi-2]) are often associated with distinct clinical disease groups and subgroups (e.g., tRNA synthetases with interstitial lung disease, Mi-2 with DM) (Table 85-3 and see Table 85-6).

Anti–histidyl-tRNA synthetase antibodies are the most frequent autoantibodies seen and are present in approximately 16% to 20% of myositis patients.[84-86] Antibodies against other aminoacyl-tRNA synthetases, such as threonyl-tRNA synthetase (PL-7), alanyl-tRNA synthetase (PL-12), isoleucyl-tRNA synthetase (OJ), glycyl-tRNA synthetase (EJ), asparaginyl-tRNA synthetase (KS), tyrosyl-tRNA synthetase (Ha), Phenylalanyl-tRNA synthetase (Zo) are found less frequently (1% to 5%). Anti–Mi-2 antibodies are strongly associated with DM,[87,88] with prominent features such as Gottron's papules, heliotrope rash, the V sign, and the shawl sign. Anti-TIF-1 gamma and anti-NXP2 are associated with CADM in adults and with JDM.[89,90,91] Anti-MDA5 antibodies are associated with clinically amyopathic DM and rapidly progressive interstitial lung disease in Asian population, whereas the clinical phenotype was less specific in Caucasians.[92]

**TABLE 85-3** Myositis-Specific Antibodies

| Autoantibodies | Clinical Disease/Features |
|---|---|
| Anti-synthetase autoantibodies* | More common in polymyositis than dermatomyositis; interstitial lung disease, arthritis, Raynaud's phenomenon, fevers, mechanic's hands |
| Signal recognition particle (SRP)† | Polymyositis; possible severe disease and cardiac involvement |
| Chromodomain helicase DNA binding proteins 3 and 4 (Mi-2α and β)‡ | Dermatomyositis |
| Anti-MDA5/Anti-CADM-140 | Dermatomyositis; mucocutaneous lesions; severe lung disease minimal muscle involvement |
| Anti-TIF1γ | Dermatomyositis; malignancy |
| Anti-nuclear matrix protein (NXP)-2/anti-MJ | Predominantly juvenile DM; joint contractures; calcinosis |
| Anti-HMG-CoA reductase | Statin-associated myopathy; necrotizing myopathy |

*Common anti-synthetase antibodies found in myositis are targeted to histidyl-tRNA synthetase (Jo-1), threonyl-tRNA synthetase (PL-7), alanyl-tRNA synthetase (PL-12), isoleucyl-tRNA synthetase (OJ), glycyl-tRNA synthetase (EJ), and asparaginyl-tRNA synthetase (KS), tyrosyl (Ha) and phenylalanyl (Zo).

†Autoantibodies commonly bind to a 54 kDa SRP protein in the U.S. patient population and 72, 54, and 9 kDa proteins in the Japanese population.

‡Targets a 240 kDa helicase protein that is part of the nucleosome remodeling deacetylase complex.

HMG-CoA, 3-Hydroxy-3-methylglutaryl-coenzyme A; MDA, melanoma differentiation associated gene 5; TIF, transcriptional intermediary factor 1 gamma; SRP, signal recognition particle.

An individual usually has only one MSA because MSAs are often mutually exclusive. The MSAs are most common in patients with other autoimmune diseases and are infrequent or absent in IBM patients and those with malignancies, muscular dystrophies, or other myopathies. These antibodies are sometimes present before the onset of clinical disease.[93] Recent studies have found that IBM patients have antibodies targeting muscle proteins, such as cytosolic 50-nucleotidase 1A (cN1A), found in one-third of IBM patients.[94,95]Another antibody reactivity found in patients with IBM-targeted desmin.[96] Other recently described autoantibodies include anti-cortactin antibodies present in patients with PM, DM, and NAM, but not with IBM.[97]

MAAs such as PM-Scl are frequently associated with a characteristic overlap syndrome that includes features of scleroderma.[98,99] This syndrome is characterized by mild muscle disease, prominent arthritis, and limited skin involvement; it frequently responds to therapy.[100] Some myositis patients also have other MAAs, such as anti-snRNP, anti-Ro/SSA, anti-Ku, and anti-PMS1. Antibodies recognizing an uncharacterized 56 kDa large nuclear ribonucleoprotein have been found in a majority of myositis patients (86%), and the antibody titer appears to vary with disease activity, suggesting its importance for our understanding of disease pathogenesis and its potential usefulness as a clinical disease marker.[101] Some of the MSAs show strong immunogenetic associations; for example, antibodies against aminoacyl-tRNA synthetases are associated with HLA-DQA1*0501, anti-Jo-1 with HLA-DRB1*03, anti-SRP with DR5, anti–Mi-2 with DR7, and anti–PM-Scl with DR3 suggesting a role of the adaptive immune system in the pathogenesis of these myositis subgroups, as a major role of the class II HLA molecules is to present antigens to T cells. Likewise HLA-DRB1 alleles (DRB1*11:01) have been found to be associated with an elevated risk for anti–HMGCR-positive statin-induced myopathy.[102] These antibodies serve as excellent clinical markers and can help diagnose and categorize these heterogeneous disorders into homogeneous subgroups.

## Cell-Mediated Immune Response

At the cellular level, there are distinct differences in the distribution and location of the various lymphocyte subsets in the muscle tissues in different IIMs. Two major patterns of inflammatory cell infiltrates are seen in muscle tissue. The first is a predominantly perivascular distribution (Figure 85-1A), often in perimysial areas (Figure 85-1C), and is largely made up of $CD4^+$ T cells, macrophages, and dendritic cells. Occasionally, B cells are present in some patients. This pattern is seen mainly in patients with DM who have skin rash, but occasionally in patients without a rash. The second pattern has a predominantly endomysial distribution (Figure 85-1B), with mononuclear inflammatory cells often surrounding and sometimes invading non-necrotic muscle fibers. These inflammatory cellular infiltrates are composed primarily of $CD8^+$ T cells and macrophages, but $CD4^+$ T cells and dendritic cells are also present. This pattern is generally seen in patients without skin rashes and often in those classified with PM or IBM. In some patients, the two patterns of inflammation are seen in the same biopsy. The two distinct locations and the varying compositions of the inflammatory cell populations in the two areas suggest two different pathogenic mechanisms—one that targets the blood vessels and one that targets the muscle fibers. Notable inflammation is also seen in other organs.

The vascular involvement in patients with DM is also manifested in the skin and can be seen clinically in the form of nailfold changes and changes in the gastrointestinal (GI) tract. The capillaries show clear hyperplasia, vacuolization, and necrosis, contributing to an ischemia that could cause

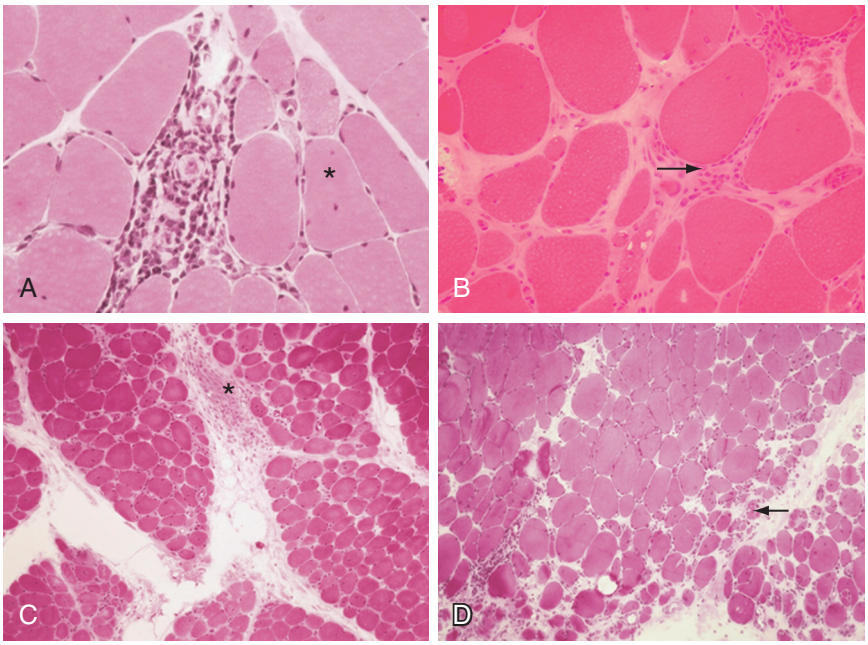

**Figure 85-1** Hematoxylin and eosin staining of a muscle biopsy showing perivascular inflammation. **A,** Variation in fiber size and central nucleation *(asterisk)*. **B,** Endomysial inflammation and increased fibrosis *(arrow)*. **C,** Perimysial inflammation *(asterisk)*. **D,** Perifascicular atrophy *(arrow)*. *(**B**, Courtesy Dr. Inger Nemmesmo. **D**, Courtesy Dr. Paul Plotz.)*

fiber damage.[103,104] One of the earliest events in the pathogenesis of DM appears to be activation of the complement cascade. This activation leads to the subsequent deposition of complement components, which in turn results in the deposition of lytic membrane attack complexes in the endothelial cells and the eventual loss of capillaries from complement-mediated damage. The capillaries are abnormally thickened and enlarged and look like high endothelial venules, which are characteristics of vessels that facilitate lymphocyte trafficking (Figure 85-2). The capillaries also show signs of neovascularization.[105] This loss of capillaries results in some of the histopathologic features characteristic of this disease: capillary necrosis and loss, perivascular inflammation and ischemia (rarely seen), and perifascicular atrophy (a late feature; see Figure 85-1C and D). Recent studies also point to a role for type I interferon (IFN)-inducible genes in the pathogenesis of DM. Plasmacytoid dendritic cells produce type I IFN and induce expression of IFN-inducible proteins such as MxA and IFN-inducible gene 15 (ISG15) in the perifascicular myofibers and capillaries of DM biopsies, suggesting that injury to muscle fibers and capillaries occurs as a result of the intra-cellular overproduction of one or more type I IFN-inducible proteins in DM.[106,107] Although no direct comparison has been reported, the pathologic changes in juvenile and adult DM appear to be similar, except that all the basic pathologic features are more prominent in the childhood form (see later in this chapter). The factors that initiate complement activation in this disease are poorly understood. However, the consequences of complement-mediated damage are clearly visible in DM.[108] Recent studies have provided evidence that type I IFN-mediated innate immunity is linked to the expression of innate immune receptors such as Toll-like receptors (TLR) (e.g., TLR-3, TLR-7, and TLR-9.) Other studies have found that class I MHC-expressing immature muscle precursors can serve as a source of type I interferon, IFN-β, in myositis. In vitro experiments have indicated that TLR-3-induced IFN-β, in combination with IFN-γ, increases the expression of class I MHC molecules, suggesting a link between the innate and adaptive immune systems in myositis.[109]

The endomysial inflammatory aggregates contain a high percentage of T cells, particularly activated $CD8^+$ T cells, macrophages, and $CD4^+$ T cells, and few natural killer cells. Immunoelectron microscopic studies have provided evidence of the invasion, replacement, and probable destruction of non-necrotic muscle fibers by T cells and macrophages.[110] Infiltrating CTLs express perforin-containing granules, which are characteristically oriented toward the target muscle fiber, indicating that muscle fiber injury may be partially mediated by perforin-dependent cytotoxic mechanisms (Figure 85-3B and C).[111] In PM and IBM, there is evidence of clonal proliferation of $CD8^+$ T cells, both within the muscle and in the peripheral circulation.[112,113] T cell lines from patients demonstrate cytotoxicity against autologous myotubes,[114] suggesting that the muscle fiber injury in PM and IBM is mediated by CTLs. CTLs are known to mediate target cell damage by both the perforin–granzyme B and Fas-FasL pathways. The overexpression of anti-apoptotic molecules, such as Bcl-2, Fas-associated death domain–like IL-1 converting enzyme inhibitory protein (FLIP) and human inhibitor of apoptosis protein–like protein, in the skeletal muscle of myositis patients suggests that perforin–granzyme B–mediated cytolytic T lymphocyte cell (CTL) damage may play a predominant role in muscle fiber injury and dysfunction in myositis.[115-117]

In contrast to previous findings, recent studies have also shown accumulations of B cells, plasma cells, myeloid dendritic cells, late-activated macrophages expressing the 25F9 marker, as well as $CD8^+$ $CD28^-$ and $CD4^+$ $CD28^-$ T cells (TCR V[β]-expanded T cells) in the skeletal muscle and peripheral circulation of patients with PM, DM, and IBM. These $CD28^-$ cells and late-activated macrophages expressing 25F9 are thought to exhibit cytotoxic potential and produce pro-inflammatory cytokines in IIM skeletal muscle.[118,119] Another study has also explored the potential role of $FOXP3^+$ Treg cells in the pathology of myositis.[120]

On the basis of the data described, two different pathways have been proposed as major mediators of muscle damage and inflammation: one mediated through T lymphocytes (CTLs) directed against muscle fibers, predominating in PM and IBM, and the other directed against vessels, predominating in DM. However, the degree of inflammation is not consistently correlated with the severity of the structural changes in the muscle fibers or with the severity of the clinical disease,[121] suggesting that nonimmune processes also play a role in disease pathogenesis. A role for nonimmune processes is supported by the following observations. First, marked structural changes in the muscle fibers occur in the absence of any inflammatory cells.[122,123] Second, there is a lack of correlation between the degree of inflammation and the degree of muscle weakness.[124] Third,

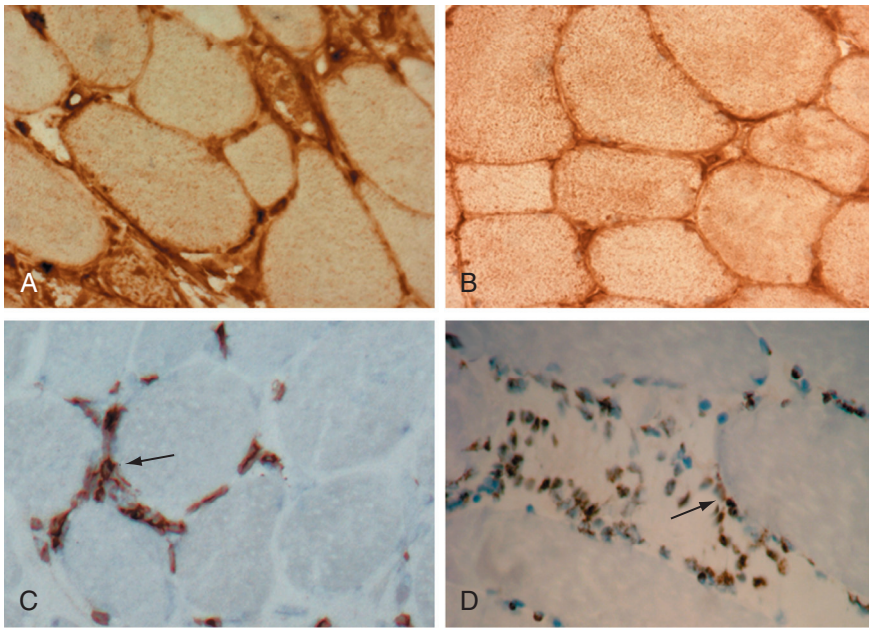

**Figure 85-3** Human leukocyte antigen (HLA)-ABC, $CD8^+$ T cell, and granzyme B staining of polymyositis biopsy. HLA expression is evident on muscle fibers, infiltrating cells, and endothelial cells **(A)**. some myositis patients do not respond even to powerful anti-inflammatory therapy.[125,126] Fourth, steroid treatment may eliminate inflammatory cells in myositis muscle tissue, but this removal alone may not substantially improve the clinical disease, suggesting that immunosuppressive therapies modulate disease activity but do not change other mediators of the disease process.[127] Finally, the clinical disease may progress when identifiable inflammation has subsided,[128] suggesting a role for nonimmune mechanisms in the pathogenesis of myositis. Thus the exact contribution of immune-mediated pathways to muscle damage is currently unknown.

## Class I Major Histocompatibility Complex Expression

Normal skeletal muscle cells do not constitutively express or display class I MHC molecules, although they can be induced to do so by pro-inflammatory cytokines such as IFN-γ or TNF[122,129-131] or by the alarmin HMGB1.[152] In contrast, in human IIMs, the early and widespread appearance of class I MHC in non-necrotic muscle cells is a striking feature, even in muscle cells distant from the lymphocytic infiltration.[122,123,132] Class I MHC staining is usually observed on the sarcolemma of muscle fibers, but some fibers also show staining in both the sarcolemma and the sarcoplasm (see Figure 85-3A and B). In some patients, the expression is restricted to a few clusters (often early in the disease), whereas in others, almost every fiber is positively stained, particularly in late-phase and treatment-resistant cases. Researchers have explored the biologic significance of these observations by generating a conditional transgenic mouse model overexpressing syngeneic mouse class I MHC. The overexpression of class I MHC molecules in the skeletal muscle of mice results in the development of clinical, biochemical, histologic, and immunologic features that resemble human myositis and provides a close model of the human disease. The disease in these mice is inflammatory, limited to skeletal muscle, self-sustaining, more severe in females, and often accompanied by MSAs.[133] Recent studies in this model further suggest that class I MHC overexpression leads to endoplasmic reticulum (ER) stress, muscle atrophy, and a decrease in the force generation capacity of skeletal muscle, suggesting a role for class I MHC muscle weakness in myositis.[134,135]

A number of observations in human myositis patients and in the mouse model of myositis suggest that class I MHC molecules mediate muscle fiber damage and dysfunction in the absence of lymphocytes. For instance, in human myositis, the induction of class I MHC antigen in muscle fibers occurs early, preceding inflammatory cell infiltration.[136,137] Class I MHC staining of human myositis biopsies shows both a cell surface and a sarcoplasmic reticulum pattern of internal reactivity, demonstrating that some of the class I MHC molecules may be retained in the ER of these fibers.[83,123,138] Persistent class I MHC overexpression in muscle fibers can exist in the absence of an inflammatory infiltrate.[128] The controlled induction of class I MHC in the mouse model is followed by muscle weakness before mononuclear cell infiltration.[133] Researchers have recently shown that in vivo gene transfer of class I MHC plasmids attenuates muscle regeneration and differentiation.[139] Together, these observations, and particularly the obvious retention of class I MHC within the cell in both human and murine disease, indicate that the muscle fiber damage seen in myositis may not be solely mediated by immune attack (e.g., CTLs, autoantibodies) but may also be mediated through nonimmunologic mechanisms such as the ER stress response and hypoxia. Activation of ER stress in cells is linked to the induction of different forms of cell death such as autophagy and apoptosis. The expression of molecules that facilitate autophagy (tumor necrosis factor-related apoptosis-inducing

ligand [TRAIL]) and apoptosis (TNF-like weak inducer of apoptosis [TWEAK]) were increased in myositis patients, providing a molecular basis for progressive muscle damage in myositis.[140,141]

In myositis, it appears that overexpression of class I MHC in myofibers initiates a series of cell-autonomous changes that contribute to myofiber pathology. Recent investigations have indicated that overexpression of class I MHC on muscle fibers results in the activation of the NF-κB and ER stress response pathways in human inflammatory myopathies and in the mouse model of myositis.[83,142] NF-κB can be activated within minutes by a variety of stimuli, including inflammatory cytokines such as TNF and IL-1, T cell activation signals, and stress inducers. It is likely that in human myositis, NF-κB activates both classic (pro-inflammatory cytokines) and nonclassic (ER stress response) pathways.[83,142-145] Furthermore, there is evidence that downstream target genes (e.g., class I MHC, intercellular adhesion molecule [ICAM], monocyte chemoattractant protein [MCP]-1) regulated by the NF-κB pathway are highly upregulated in myositis patients.[138,146,147] Recent studies have indicated that NF-κB p65 is activated both in human myositis biopsies and in the mouse model,[83,142,148,149] suggesting that this pathway may be directly involved in muscle fiber damage (Figure 85-4).

## Cytokines and Hypoxia

A number of other effector molecules produced in muscle tissue by inflammatory cells, endothelial cells, and muscle fibers are thought to play a role in the pathogenesis of myositis.[80] Most of the data assembled relate to cytokines, but some data related to chemokines are also available. The most consistently demonstrated cytokines in muscle tissue from patients with IIMs are cytokines with pro-inflammatory properties: IL-1α, IL-1β, TNF, and IFN-α. Recently, IL-10, IL-13, epidermal growth factor (EGF), vascular endothelial growth factor (VEGF), fibroblast growth factor (FGF), CCL3 (macrophage inflammatory protein [MIP-1α]), CCL4 (MIP-1β), CCL11 (eotaxin), IL-15, and IL-15Rα were also demonstrated to be significantly upregulated, and granulocyte colony-stimulating factor (G-CSF) to be downregulated in patients with IIMs when compared with unaffected individuals.[150,151] Also, DNA-binding high mobility group box 1 (HMGB1) was found to exhibit both extranuclear and extra-cellular patterns in the muscle tissue of patients with PM and DM. Stimulation with IFN-γ showed an increased HMGB1 expression in muscle nuclei and myoplasm. Exposure to HMGB1 induced a reversible upregulation of class I MHC in the muscle fibers and an irreversible decrease in $Ca^{2+}$ release from the sarcoplasmic reticulum during fatigue, suggesting a role for HMGB1 and class I MHC early in the pathogenesis of IIMs.[152] In addition to inducing the upregulation of class I and II MHC molecules on muscle fibers, cytokines can have a direct effect on muscle fiber function, as has been demonstrated for TNF.[153] The relative importance of the various cytokines and chemokines in patients with myositis is still uncertain, but these molecules are potential biomarker candidates in this disease, as has been indicated by a recent study showing that serum IL-6 production and the type I IFN gene signature in the peripheral blood are correlated with disease activity in patients with DM.[154] Recent studies provide evidence on how pro-inflammatory cytokines such as TNF decrease myogenic miRNAs (e.g., miR-1, miR-133a, miR-133b, and miR-206) and facilitate muscle degeneration in myositis.[155]

Microvessel involvement was first observed in DM but has also become evident in PM. The endothelial cells in both subsets show increased expression of adhesion molecules and pro-inflammatory cytokines such as IL-1α. This phenotype can be induced by tissue hypoxia, which may result from capillary loss and local tissue inflammation. Muscle tissue hypoxia can contribute to the clinical symptoms and muscle fatigue, and may be associated with disease mechanisms in inflammatory myopathies.[80] The expression of VEGF receptor in muscle fibers and HIF-2α reactivity in the endothelial cells of patients with PM and IBM support a role for hypoxia in these conditions. Patients with DM showed hypoxia-inducible factor (HIF)-1α and HIF-1β expression in endothelial cells, whereas expression of HIF-2α, erythropoietin receptor, VEGF, and VEGF-R were also observed on muscle fibers. These observations suggest that deprivation of blood supply by immune-mediated mechanisms could trigger the upregulation of hypoxia-related proteins as an adaptive response.[156] In

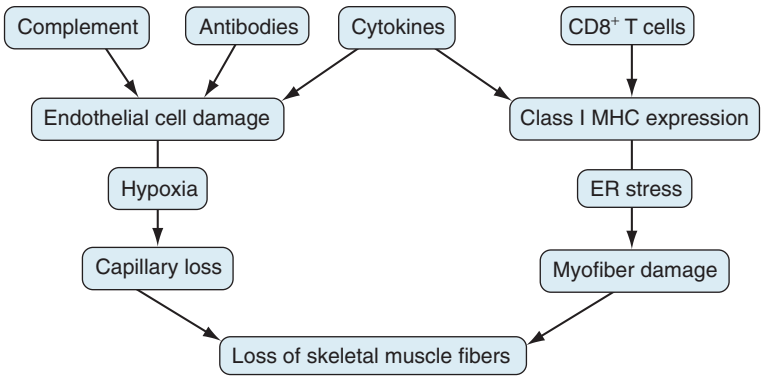

**Figure 85-5** Mechanisms of muscle fiber damage in myositis. ER, Endoplasmic reticulum; MHC, major histocompatibility complex.

addition, magnetic resonance spectroscopic analysis, before and after a workload, has demonstrated reduced levels of energy substrates that are important for muscle contraction, such as adenosine triphosphate and phosphocreatine, when compared with the levels in healthy individuals. This finding supports the hypothesis that an acquired metabolic disturbance occurs in chronic inflammatory myopathies, and that this disturbance can contribute to impaired muscle performance.

Microarrays have provided considerable new insight into DM. Early on, mRNA profiling in DM showed a predominance of type I IFN-responsive pathways, suggesting the possible persistence of an anti-viral response.[205] Particularly prevalent was the dramatic expression of the IFN-inducible MxA gene. This signature was confirmed and extended,[206] supporting an important role of the innate immune response, with prominent plasmacytoid dendritic cell infiltration in DM when compared with the other inflammatory myopathies.

### Proposed Mechanisms of Muscle Damage

Currently available data suggest that both immune (cell-mediated and humoral) and nonimmune (ER stress, hypoxia) mechanisms play a role in muscle fiber damage and dysfunction in myositis. Innate immune cell activation occurs as a result of injury to skeletal muscle, resulting in the release of damage-associated molecular patterns (DAMPs). TLR signaling activates various antigen-presenting cells (APC) in the muscle. These APCs then activate CD4 T cells and initiate autoantigen-specific T cell responses and autoantibody responses. Class I MHC overexpression on muscle also leads to the activation of CD8 T cell mediated cytotoxicity. DAMPs bind to surface or endogenous TLRs expressed in muscle-infiltrating immune cells, capillaries, and fibroblasts. TLR signaling activates NF-κB and inflammasomes, resulting in the production of pro-inflammatory cytokines, chemokines, and adhesion molecules. Cytokines such as TNF can directly induce the death of muscle cells and also effectively inhibit myogenesis through microRNAs. TLR signaling also leads to inflammasome activation (IL-1 secretion) and, potentially, to induction of pyroapoptosis in the affected muscle, whereas activation of TRAIL induces autophagy in the muscle. Unknown cytokines reduce the expression of rate-limiting enzymes of the purine nucleotide cycle and of AMPD1 in skeletal muscle. This acquired deficiency of APMD1 is likely to cause muscle weakness and fatigue in patients with myositis. In addition, class I MHC accumulation in the ER induces the ER stress response in muscle. Thus, several immune, nonimmune, and metabolic pathways directly and indirectly contribute to muscle weakness and damage in myositis. The relative contribution of each of these pathways to muscle fiber damage is presently unclear (Figure 85-5). Therefore, the use of specific drugs to inhibit these pathways, either alone or in combination, would help define their roles in myositis and potentially show them to be effective therapeutic agents.

## CLINICAL FEATURES

The inflammatory myopathies can occur as distinct disease entities, or they can coexist with some other rheumatic disease. This observation is true for all three subsets of myositis, but it is most often seen in PM and DM. The rheumatic diseases most often associated with inflammatory myopathies are systemic sclerosis, mixed connective tissue disease, Sjögren's syndrome, and SLE; however, rheumatoid arthritis may also be associated with inflammatory myopathies. IBM may be associated with Sjögren's syndrome, SLE, and other autoimmune diseases.[130,158] Because the clinical features of IBM differ somewhat from those of PM and DM, they are discussed separately, as are necrotizing myopathies.

### Polymyositis and Dermatomyositis

The predominant symptoms in patients with PM or DM are muscle weakness and low muscle endurance. The weakness is most pronounced in proximal muscle groups—typically in the neck, pelvic area, thigh, and shoulder muscles—with a symmetric distribution. Patients generally experience more problems with performing repetitive movements than with single-strength exercises, and they report difficulty walking uphill or upstairs, working with their arms above their shoulders, or rising from chairs. Also, distal muscles may be involved in PM and DM, affecting grip strength and health-related quality of life.[159] The onset of muscle weakness is often subacute, occurring during a few weeks, or it can be insidious, developing during several months. If

untreated, the muscle weakness slowly progresses, and in the most severe cases, the patients may become wheelchair-dependent. Problems with swallowing and nutrition can occur as a result of impaired contractility of the throat muscles, potentially leading to aspiration pneumonia. In rare cases, patients experience difficulty breathing because of weakness of the diaphragm or thoracic muscles, and they may require assisted ventilation. Other striated muscles may be involved, such as in the lower part of the esophagus (causing reflux problems) or the sphincter ani (causing incontinence).

### Skin

DM is characterized by the presence of certain types of rashes[160]; the same types are often seen in both children and adults. The most specific skin manifestations are Gottron's papules and the heliotrope rash (Figure 85-6). Gottron's papules are slightly elevated, violaceous, pink, or dusky red papules located over the dorsal side of the metacarpal or interphalangeal joints. These papules may also occur over the extensor side of the wrist, elbow, or knee joints. Gottron's papules are considered to be pathognomonic of DM. A macular rash (without papules) with the same distribution as Gottron's papules is called *Gottron's sign* (see Figure 85-6C and D). The heliotrope rash is a periorbital red or violaceous erythema of one or both eyelids, often with edema (see Figure 85-6B). Linear erythema overlying the extensor surfaces of joints is also relatively specific to DM (Figure 85-7A). Many patients with DM have photosensitive rashes, typically found on the face or scalp or over the neck (the so-called *V sign*), although this rash is not specific to DM (see Figure 85-7B and C). Another common rash in DM is located over the shoulders (shawl sign; Figure 85-7D) or over the hips (holster sign). Pruritus is common. Patients with DM often have skin lesions on their fingers, such as periungual erythema, nailfold telangiectasias, and cuticular overgrowth (Figure 85-8C), and this development can even lead to digital ulceration. Other less common skin manifestations are panniculitis, livedo reticularis, and nonscarring alopecia. Vasculitis may be seen in children with DM, but only rarely in adults.

In general, the skin rash is moderate, with local erythema. In rare cases, a severe, diffuse erythema (erythroderma) can occur, occasionally with vesiculobullous lesions or ulcers. The skin rash can precede the muscle symptoms by months or even years, and in some patients, the skin manifestations may be the only clinical sign of DM. This condition is often called *clinically amyopathic DM* or *DM sine myositis* (see following text). The pattern of the rash over the knuckles and dorsum of the hand is distinct in SLE and DM. The rash in DM generally spares the phalanges but affects the knuckles, whereas in SLE the rash is located over the phalanges but the knuckles are spared (see Figure 85-8A and B). However, no histopathologic skin features are specific for DM; most of the features are also seen in patients with SLE. Thus skin biopsy is rarely helpful in distinguishing between these two disorders. The cutaneous manifestations may fail to respond to immunosuppressive treatment, despite improvement in muscle symptoms. Thus it is possible that different molecular pathways or disease mechanisms cause the skin rash and the muscle inflammation.

Calcinosis, which can be severe, is found mainly in juvenile DM but is occasionally seen in adults. The calcinosis occurs predominantly in sites that have been subject to friction or trauma, such as the elbows or knees. Sometimes the calcinosis can be extensive and erupt, leading to ulcers. It is most often localized to the subcutaneous tissue but can also develop in the skin, fascia, or muscle and can be visualized by radiography, CT, or MRI. The calcinosis seems to progress as long as there is active inflammatory disease.

Also, once it has developed, it is often treatment resistant. Some data, however, suggest that the progress of calcinosis can be inhibited by effectively treating the inflammatory process in the skin and muscle.[161]

Another type of skin pathology seen in inflammatory myopathies is called *mechanic's hands*. This rash is often associated with the presence of anti-synthetase autoantibodies and can be seen in both PM and DM. The rash is a hyperkeratotic, scaling, fissuring of the fingers, particularly on the radial side of the index fingers (Figure 85-9).

## Lungs

Lung involvement is frequent in PM and DM and is a major risk factor for morbidity and mortality. Clinical symptoms such as dyspnea and cough are common. Lung involvement can be caused by weakness of the respiratory muscles or inflammation of the lung tissue (ILD). Weakness of the respiratory muscles may lead to restrictive lung disease, and involvement of the pharyngeal muscles is a risk factor for aspiration pneumonia. ILD, caused by inflammation in the small airways, is common in PM and DM and is often associated with anti-synthetase autoantibodies. It may be present in as many as 70% of patients when investigated with sensitive techniques such as high-resolution CT and measurement of pulmonary function and diffusion capacity.[162] In most cases, the changes are present at the time of diagnosis of myositis; they rarely develop after immunosuppressive treatment has started. In most cases, the ILD is mild and has a slowly progressive course. Anti-synthetase and anti-MDA5 antibodies are strongly associated with ILD, and thus serve as biomarkers for ILD. In some cases, improvement in lung function is seen with immunosuppressive treatment. The course and outcome vary depending on the histopathology, suggesting that different disease mechanisms cause ILD.

In general, the clinical course and histopathology of ILD in myositis are no different from those in idiopathic ILD. The most common histopathologic finding is nonspecific interstitial pneumonia, but other entities such

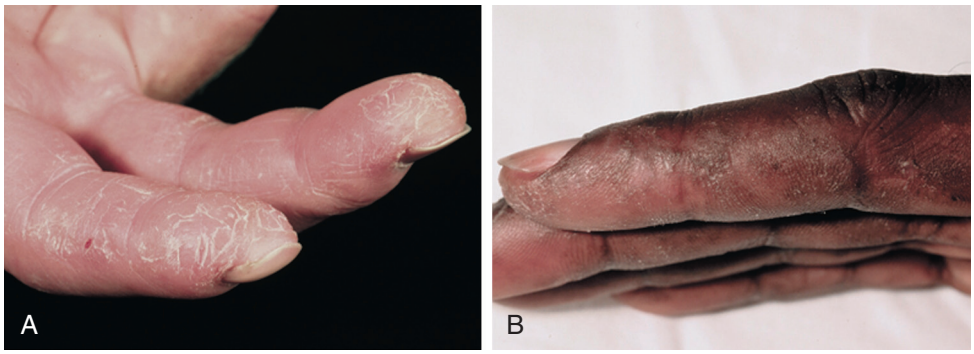

**Figure 85-9** Mechanic's hands in a white **(A)** and a black **(B)** patient. Note the characteristic skin changes on the lateral side of the fingers. *(Courtesy Dr. Paul Plotz.)*

as cryptogenic organizing pneumonia, bronchiolitis obliterans organizing pneumonia, diffuse alveolar damage, and usual interstitial pneumonia are also found. Some studies suggest that bronchiolitis obliterans organizing pneumonia responds favorably to corticosteroids, whereas histopathologic changes compatible with diffuse alveolar damage, usual interstitial pneumonia, or acute interstitial pneumonia respond poorly to corticosteroids or other immunosuppressive therapies and have a poor prognosis.

### Arthritis

Joint pain and arthritis are common in patients with PM or DM. The most common form of arthritis is a symmetric arthritis of the small joints of the hands and feet. This arthritis is typically nonerosive but can sometimes be erosive and destructive. Most frequently, arthritis is seen in patients with anti–Jo-1 antibodies and other anti-synthetase autoantibodies, but it is also seen in patients with overlapping syndromes of other rheumatic diseases.

### Heart

Cardiovascular disease is a risk factor for death among patients with PM and DM. However, clinically evident heart involvement is rare, perhaps indicating that cardiac involvement may be overlooked in these conditions. Subclinical manifestations are frequently discovered when patients with PM or DM are evaluated. The most frequently reported subclinical manifestations are conduction abnormalities and arrhythmias detected by electrocardiogram (ECG), and subclinical cardiomyopathies are common when cardiac MRI is performed, even in patients thought to be in remission.[163] The underlying pathophysiologic mechanisms that can lead to cardiac manifestations in patients with PM or DM are myocarditis and coronary artery disease, as well as involvement of the small vessels of the myocardium.

Examination with ECG is recommended in patients newly diagnosed with PM or DM. Serum tests such as CK-myocardial band (CK-MB) to detect cardiac involvement are unreliable in patients with inflammatory myopathies because CK-MB can be released from regenerating skeletal muscle fibers, a common feature in biopsies from patients with PM or DM. The CK-MB/total CK ratio may be greater than 3%, a threshold value that is used to define myocardial damage. A more specific marker for myocardial damage in myositis patients is increased serum levels of cardiac isoform troponin I. The other cardiac troponin isoforms, troponin C and troponin T, are less specific and are also expressed in adult skeletal muscle; increased serum levels have been reported in various muscle disorders.

### Gastrointestinal Tract

Difficulty swallowing is frequent in patients with inflammatory myopathies, particularly those with IBM. Muscle weakness occasionally becomes severe and causes problems with nutrition and aspiration pneumonia. The pathophysiology is related to weakness in the tongue, pharyngeal muscles, and sometimes lower esophagus. Reflux that requires special care is common, occurring in 15% to 50% of patients. Constipation, diarrhea, and stomach pain are common symptoms and may result from disturbed motility of the gut or GI tract inflammation. Vasculitis in the blood vessels of the GI tract is rare but may be complicated by intestinal bleeding.

### Anti-synthetase Syndrome

MSAs are strongly associated with clinical phenotypes and may thus be helpful to identify clinical subsets of myositis. The most common of the MSAs are the anti-synthetase autoantibodies directed against aminoacyl-tRNA synthetases (anti-Jo-1, anti-EJ, anti-PL-7, anti-PL-12, anti-KS, anti-OJ, anti-Ha, and anti-Zo).[164] A clinically distinct subset of myositis, often called anti-synthetase syndrome, has been identified in patients with anti-synthetase autoantibodies.[39,67] The most common of the anti-synthetase autoantibodies is anti–Jo-1, which is directed against histidyl-tRNA synthetase. This autoantibody is present in approximately 20% of patients with PM or DM, but is only rarely found in patients with IBM.[84] Anti-synthetase syndrome is characterized by the presence of anti-synthetase autoantibodies and a set of clinical features that includes myositis, ILD, Raynaud's phenomenon, nonerosive symmetric polyarthritis of the small joints, and mechanic's hands (see Figure 85-9). Notably, some of the anti-synthetase autoantibodies are mainly associated with ILD (anti-PL12), and these patients with ILD may be missed as having an anti-synthetase syndrome in the absence of muscle symptoms.

### Amyopathic Dermatomyositis

A subset of DM is clinically referred to as *amyopathic DM*. These patients have a skin rash, which is typical of DM, but no clinical signs of muscle involvement.[165] The proposed definition is based on a skin biopsy consistent with DM and a duration of 6 months or longer in the absence of clinical or laboratory evidence of myositis. Some of these patients do have subclinical myositis, based on MRI or biopsy findings at presentation; others manifest clinically overt myositis sometime later. Patients without clinically overt myositis, however, can develop extramuscular manifestations such as ILD, which can be severe. Amyopathic DM may be associated with malignancies, as is the case for classic DM. The frequency of this subset is uncertain, but some recent studies suggest that this form of DM may be more common than previously thought.

### Juvenile Dermatomyositis

The incidence of juvenile dermatomyositis (JDM) is between 1.7 and 3 per million children and is the most common IIM in children; PM and overlap myositis are much less common and have a poorer prognosis. Malignancy-associated myositis is very rare in children, accounting for less than 1% of all IIM.[166] Because JDM accounts for 85% of all cases of juvenile IIM, we will focus on it here. The disease onset has two peaks—age 6 and 11 years. JDM is more common in girls than in boys in Europe and North America; in Japan and Saudi Arabia, this difference is less prominent. The diagnosis is based on clinical and laboratory parameters, because most children do not undergo electromyelograms or muscle biopsies. The discovery of more myositis-specific antibodies means that they can currently be found in more than 70% of all children with JDM. Anti-TIF-1γ and anti-MJ antibodies are the most prevalent in JDM compared with adult DM.[167,168] The most common clinical manifestations at disease onset are muscle weakness, easy fatigability, skin rash, malaise, and, in some cases, fever.[161] The CK levels tend to be mildly elevated. The skin rash is often pathognomonic and similar to that in adult DM: the most typical skin manifestations are heliotrope discoloration of the upper eyelids, Gottron's papules, periungual erythema, and capillary loop abnormalities (dilated and tortuous with decreased capillary density). Calcinosis, cutaneous ulceration, and lipodystrophy are more common in juvenile cases than in adults. Calcinosis is seen in 30% to 70% of children with JDM, and the presence of anti-NXP2 autoantibodies increases the risk of calcinosis and is associated with more aggressive disease.[169] In addition, a delay in diagnosis, cardiac involvement, and a prolonged disease course increase the risk of calcinosis.[170] The calcinosis is most often located at sites exposed to trauma and can be seen in the skin, fascia, or muscles. In some children, the calcinosis becomes prominent and causes contractures and ulcerations. Vasculopathy that affects the GI tract, with ulceration, perforation, or hemorrhage, is rare but seems to be more common in children than in adults with DM. Because this vasculopathy can be a serious sign, screening for GI involvement should be included in the evaluation of patients with JDM. ILD is rarely seen in JDM.

Recently validated core set measures have allowed the Childhood Arthritis and Rheumatology Research Alliance (CARRA) to develop consensus guidelines for the treatment of JDM.[171,171] Daily prednisone starting at 2 mg/kg/d is considered first-line therapy, with intravenous (IV) methylprednisolone, methotrexate, and IVIG used as adjunct therapy for first-line treatment of severe JDM. Mycophenolate mofetil, tacrolimus, and rituximab are used for refractory disease, and IV Cytoxan is used for refractory life-threatening disease. The overall prognosis is variable. The mortality rate is estimated at 2% to 3%, with 24% to 40% of patients going into remission within 2 years (allowing cessation of immunosuppressive therapy). However, the majority of patients have a chronic course.[167,172-174] Side effects of immunosuppressive treatment such as growth failure are common.

## Inclusion Body Myositis

IBM is distinguished from PM and DM on the basis of both clinical and histopathologic features.[175,176] Sporadic IBM is a distinct entity from familial hereditary inclusion body myopathy, which shares some of the same clinical and histopathologic features but lacks signs of inflammation in muscle tissue. IBM was identified in the 1960s as a subset of inflammatory myopathies, distinct from PM, primarily on the basis of typical histopathologic features that include sarcoplasmic and nuclear inclusions and rimmed vacuoles.[16,17] A characteristic clinical phenotype was later identified, characterized by an insidious onset of muscle weakness (localized predominantly to the thigh muscles and finger flexors) during months to years and resistance to glucocorticoid treatment. IBM patients often have a history of frequent falling. Sporadic IBM cases are sometimes misdiagnosed as PM because the classic histopathologic changes (rimmed vacuoles and inclusions) may not be evident in early biopsies (Figure 85-10).

In contrast to PM and DM, IBM is more frequent in men than in women, and it is seen mostly in individuals older than 50 years. The onset is more insidious than that of PM or DM. Patients with IBM rarely have pain. The most frequent initial symptoms are difficulty climbing stairs and walking uphill and frequent falls as a result of weakness in the knee extensor muscles. Muscle weakness may become prominent, and even walking across a threshold may become a problem. Difficulty swallowing may also be an early clinical feature, reflecting the involvement of the pharyngeal muscles. The course is slowly progressive, leading to muscle atrophy that can be striking, particularly in the thigh and forearm muscles. Severe weakness may develop, and many patients become wheelchair-dependent. Extramuscular organ involvement is rare, although a subgroup of patients with IBM has sicca symptoms and may develop a secondary Sjögren's syndrome.[177] IBM is usually resistant to treatment with glucocorticoids and other immunosuppressive agents. Because of this resistance to treatment, some have questioned whether IBM is an autoimmune disease or a degenerative muscle disease supported by the abnormal accumulation of proteins such as amyloid-β in muscle fibers. This issue is still under debate and is the subject of ongoing research in several institutions around the world.

### Necrotizing Myopathies

In the past decade, another subset of immune-mediated myositis has been identified and is defined by presence of autoantibodies; anti-SRP antibodies or anti-HMG-Co A reductase antibodies and by predominating muscle fiber necrosis without the classic lymphocytic infiltration in muscle biopsies seen in other IIM.[178,179] Patients who have antibodies to 3-hydroxy-3-methylglutaryl-coenzyme A reductase (HMGCR) can be further divided into those who have a history of statin exposure and those who are statin-naïve (non–statin-induced necrotizing myositis). Presence of autoantibodies together with an upregulation of class I MHC in the muscle fibers and by deposition of complements on capillaries are suggestive of an autoimmune etiology of a necrotizing myopathy, but they can also be seen in anti-synthetase syndrome or DM.[180,181] A necrotizing muscle biopsy can also be seen in other nonautoimmune etiologies, including hypothyroidism, heritable myopathies, and toxic myopathies or cancer-associated myopathies.[182]

### Statin Myopathy

Statins (e.g., lovastatin, simvastatin) are lipid-lowering drugs that are known to cause necrotizing myopathy. Most cases of statin myopathy resolve with cessation of therapy. However, statins have also been linked to a more severe autoimmune myopathy that is associated with necrotizing myopathy on biopsy, severe progressive proximal muscle weakness with an elevation in CK, and autoantibodies to HMGCR. This antibody, however, is not found in most patients who are exposed to statins and have no autoimmune myopathy, even those with mild myalgias.[183] This form of statin myopathy requires immunosuppressive therapy. Other agents that are known to cause necrotizing myopathy include fibric acid derivatives (clofibrate, gemfibrozil), nicotinic acid, organophosphate poisoning, and ε-aminocaproic acid.

### Non–Statin-Induced Necrotizing Myopathy

Non–statin-induced necrotizing myopathy occurs in a subset of patients who are statin-naïve, develop a necrotizing myopathy, and have HMGCR antibodies. These patients tend to be younger, have high CK levels, and respond less well to immunosuppressive therapy.[184]

## Myositis Associated with Malignancies

An association between DM and malignancies was observed in several early case reports. The clinical implications of this association, irrespective of the pathophysiologic mechanisms involved, are that it is imperative to screen for tumors in patients with DM at the time of diagnosis and at relapse, particularly if the symptoms do not respond to conventional immunosuppressive treatment. Two myositis-specific autoantibodies are associated with DM and malignancies in adults: anti-TIF1gamma and anti-NXP2.[185,186] The types of malignancies vary and include not only hematologic malignancies such as lymphoma but also solid tumors such as lung, ovarian, breast, and colon cancer. For women, mammography and a gynecologic examination should be conducted as well. If any abnormalities are found, physicians should guide a more thorough investigation for malignancies. Ethnic backgrounds should be considered in screening, because cancer types vary according to race, with lung and nasopharyngeal cancers being more frequent in Asians than Caucasians.[187]

## CLASSIFICATION AND DIAGNOSTIC CRITERIA

At present, there are no prospectively validated diagnostic or classification criteria for myositis. Dividing diseases into homogeneous subsets serves several important functions, including allowing us to estimate disease incidence and prevalence, understand disease pathogenesis and natural history, and evaluate the patient's response to therapy and prognosis. More than three decades ago, Bohan and Peter[14,15] proposed a set of five criteria to facilitate the diagnosis of IIM patients (Table 85-4). They classified IIMs into five groups: primary idiopathic PM, primary idiopathic DM, IIMs associated with malignancy, childhood IIMs associated with vasculitis, and IIMs associated with collagen vascular diseases. The exclusion criteria were signs of central or peripheral neurologic disease, a family history of muscle disease (although familial myositis has been reported in dozens of cases), and symptoms and signs suggestive of muscular dystrophy, granulomatous myositis, infections (including trichinosis, schistosomiasis, trypanosomiasis, staphylococcal infection, and toxoplasmosis), drug-induced myopathy, toxic myopathy, rhabdomyolysis, metabolic disorders, endocrinopathies, myasthenia gravis, and myositis after viral infection (influenza or rubella). A weakness of

the Bohan and Peter classification is that it overdiagnoses patients with PM and loosely defines overlap syndromes.

Despite their several drawbacks, these criteria have served well in diagnosing and defining patients for research purposes for the past 3 decades. IBM was later recognized as a separate disease entity characterized by a slow onset and progression involving finger flexors or the quadriceps muscles that may be asymmetric.[175,176] It can occur as a stand-alone entity or with other connective tissue diseases, and patients are often resistant to steroid therapy. Other focal and diffuse forms of myositis, such as orbital myositis, focal nodular myositis, macrophagic myositis, and eosinophilic myositis, are relatively rare.

**TABLE 85-4** Bohan and Peter Criteria for Polymyositis and Dermatomyositis

| |
|---|
| Exclude all other myopathies |
| Symmetric proximal muscle weakness |
| Increase in serum muscle enzymes, such as CK, AST, ALT, aldolase, and LDH |
| Abnormal electromyographic findings, such as short, small, polyphasic motor units; fibrillations; positive sharp waves; insertional irritability; and bizarre high-frequency repetitive discharges |
| Abnormal muscle biopsy findings, such as mononuclear infiltration, regeneration, degeneration, and necrosis |
| Skin rashes, such as heliotrope rash, Gottron's sign, and Gottron's papules |

ALT, Alanine transaminase; AST, aspartate transaminase; CK, creatine kinase; LDH, lactate dehydrogenase.

Since Bohan and Peter proposed their classification criteria, advances in clinical research have led to the identification of certain autoantibodies that are strikingly associated with some clinical phenotypes of myositis (see Table 85-3). The identification of clinical features associated with MSAs and MAAs has led to the proposal of a serologic approach to complement the Bohan and Peter classification system. Others have suggested that the Bohan and Peter criteria be modified to add MSA as a criterion.[188] However, the inclusion of MSA has some limitations. These antibodies are not present in all patients, the immunoprecipitation techniques that are the "gold standard" for identifying these antibodies are available in only a few commercial laboratories, and the enzyme-linked immunosorbent assays often used can give false-positive or false-negative results.

Ongoing debate and dialogue within the scientific community about the nature of the diagnostic and classification criteria that could better define these disorders is extensive.[78,189,190] Some schemes emphasize a focus on histopathologic features, and others on autoantibody profiles. Certainly, the addition of autoantibody profiles, characteristic histopathologic and immunohistochemical features, and imaging techniques such as MRI would significantly strengthen the current criteria and better define these disorders (Table 85-5).

**TABLE 85-5** Clinical and Laboratory Features of Idiopathic Inflammatory Myopathy Subgroups

| Diagnostic Features | Dermatomyositis | Polymyositis | Inclusion Body Myositis | Necrotizing Myopathy |
|---|---|---|---|---|

*Rarely in children.
†Early involvement of finger flexor, wrist flexor or wrist extensor weakness, and involvement of quadriceps femoris.
‡Some patients have dysphagia, synovitis, and interstitial lung disease.
§Some patients have dysphagia.
‖Gottron's sign and heliotrope rash.
¶Especially in children.
**Overlap with scleroderma, systemic lupus erythematosus, rheumatoid arthritis, Sjögren's syndrome, and mixed connective tissue disease.
††Associated with Sjögren's syndrome but less frequently associated with other connective tissue diseases.
‡‡Dermatomyositis is more frequently associated with cancer than are polymyositis and inclusion body myositis and not overrepresented in polymyositis or inclusion body myositis.
§§Serum creatine kinase, aspartate transaminase, lactate dehydrogenase, and aldolase vary from normal to very high levels.
‖‖Myopathic motor unit potentials with spontaneous discharges in dermatomyositis, with and without spontaneous discharges in polymyositis, and mixed pattern of short- and long-duration motor unit potentials in inclusion body myositis.
EMG, Electromyogram; MHC, major histocompatibility complex; ?, association between PM/IBM and malignance is not clear; ??, necrotizing myopathy (other than autoimmune necrotizing myopathy) can be associated with cancer.

Recently, the American College of Rheumatology (ACR) and the European League against Rheumatism (EULAR) supported a multidisciplinary collaboration, the International Myositis Classification Criteria Project (IMCCP). Retrospective case-control clinical and laboratory data were collected from more than 47 clinics worldwide and were both internally and externally validated. Two models were used: one used clinical evaluation of muscle and skin and laboratory evaluations, and the second model used these variables as well as muscle biopsy results. These models resulted in a high sensitivity and specificity and performed better than the existing Bohan and Peter classification. Moreover, they also performed well in classifying the more recent recognized subgroups, clinical amyopathic DM and the immune-mediated necrotizing myopathy.[192]

## PHYSICAL FINDINGS

Although most patients are first seen with muscle weakness or fatigue, the IIMs are systemic connective tissue diseases, and other organs are frequently involved; therefore, the physician should conduct a full clinical examination when patients are seen with muscle symptoms. This examination could also be helpful in distinguishing IIMs from noninflammatory myopathies.

The muscle problems reported by many patients consist of not only muscle weakness but also muscle fatigue or reduced muscle function. Thus, the evaluation must differentiate between strength and fatigue by evaluating muscle strength and testing repetitive movements for muscle fatigue. In the early phases, atrophy is usually not a pronounced phenomenon in PM or DM. In later phases, a moderate symmetric atrophy of proximal muscles may be present. Asymmetric atrophies indicate conditions other than inflammatory myopathies. More severe atrophy of the quadriceps muscles and the flexor muscles of the forearms, which may be asymmetric, often develops in patients with IBM, and deformities in the finger joints and difficulty making fists may also develop.

Muscle strength can be tested in various ways. The physician can quickly screen for weakness in proximal lower leg muscles by asking the patient to stand up from a sitting or squatting position without support. A more standardized test that is easy to perform in the clinic is the manual muscle test, with grading according to the Medical Research Council (MRC) scale. There are many variants of this test, but a short form, addressing eight muscles on the dominant side, is recommended as part of the disease activity score by the International Myositis Assessment and Clinical Studies (IMACS).[193] In many patients with PM or DM, muscle strength as assessed by the manual muscle test is good in most of the tested muscle groups. Typically, moderate muscle weakness is seen in the neck flexors and hip girdle muscles. Testing that involves a number of repetitions is often a more sensitive method of detecting muscle impairment. The Functional Index in Myositis-2 is a myositis-specific outcome measure that assesses a number of repetitions. With this test, proximal muscle groups are more involved than are distal muscles. This index is often used by physical therapists.[194] In patients with IBM, knee extensors and finger flexors are often weak.

The physician should also examine the skin to detect changes, including those in nailfolds and the scalp. Joints can be affected by arthritis, and heart and lung changes should be carefully looked for.

## LABORATORY FINDINGS

Laboratory evaluations are critical components of both diagnosis and patient management. Combinations of laboratory tests are generally used during patient evaluations. Because no laboratory test is highly specific for IIMs, the results of these tests are usually interpreted in the clinical context.

### Biochemical Tests

Measuring serum levels of muscle enzymes is an important part of the evaluation of patients with myositis. Elevated levels of muscle-derived serum enzymes reflect ongoing damage to the muscle parenchyma. These measurements help differentiate IIMs from conditions such as steroid myopathy and denervation, in which atrophy is a prominent feature.[195] Measurement of the serum CK level is traditionally the first step in the assessment of patients with IIM. CK exists as MM (skeletal muscle), MB (cardiac muscle), and BB (brain) isoforms in serum. In comparison with other serum muscle enzymes, CK appears to be a relatively specific and sensitive indicator of the degree of muscle fiber injury. However, the range varies significantly among patients, with levels being normal in some patients and elevated by several hundred-fold in others.

Generally, 80% to 90% of adult myositis patients show an increase in CK during the initial evaluation. However, a certain proportion of patients, especially those in advanced stages of the disease, show normal or relatively modest elevations in CK, in part because of a lack of muscle mass or the presence of inhibitors of CK activity.[196,197] Normal CK is relatively more common in DM than in PM. In the absence of CK elevation, it is usually easier to diagnose DM than PM because of the presence of skin rashes in the former. It is also known that CK levels are generally lower in patients with IBM than in those with PM or DM. Therefore, a normal CK level does not exclude a diagnosis of IIM, particularly IBM or DM.

Constantly elevated levels of CK are often a sign of inflammatory activity. A rise in CK level is generally correlated with overall disease activity during time, but not with strength or functional measures of disease activity.[198,199] CK measurements are usually not useful for monitoring disease exacerbations, and they should always be evaluated in the clinical context. CK levels may normalize without clinical improvement, or they may increase without clinical worsening; however, increasing levels point to a potential flare and warrant closer clinical evaluation. CK elevations are not specific for myositis because this enzyme is also elevated in other muscle diseases, including muscular dystrophies, rhabdomyolysis, hypothyroidism, and many drug-induced myopathies. The cardiac isoform troponin I has the highest specificity as an indicator of myocardial involvement and is the most reliable serum marker for detecting myocardial damage in patients with inflammatory muscle disease.[200]

Measurement of other serum muscle enzymes, including aldolase, aspartate transaminase (AST), alanine transaminase (ALT), and lactate dehydrogenase (LDH), significantly improves the chance of diagnosing myositis, especially in patients with active disease and normal CK levels. Aldolase, LDH, and AST are better correlated with disease activity in patients with JDM. The main disadvantage of these enzymes is that they are also elevated in liver diseases; therefore, the muscle source needs to be identified before interpreting the data.[201]

The serum myoglobin level is a sensitive index of muscle fiber membrane integrity, and can therefore be used to assess the degree of disease activity. The advantage of the myoglobin assay is that it involves a nonenzymatic immunologic reaction. The disadvantages are that a significant range of serum myoglobin levels occurs in myositis patients because of circadian variation,[202] and the test is less readily available than CK for routine use.

## Histopathology

Muscle biopsy is the "gold standard" for the diagnosis of inflammatory myopathies and a critical component of the definitive diagnosis of IIMs.[203,204] For optimal biopsy results, it is important to select a muscle that is moderately weak. The histologic features can be grouped into general features that are common to all IIMs and specific features unique to a particular subgroup. The general features include necrosis, regeneration, degeneration, variation in fiber diameter, increase in connective tissue, and inflammation. The features specific to DM include loss of capillaries, alterations in the morphology of the capillaries, capillary necrosis with the deposition of complement products (e.g., membrane attack complex) on the vessel walls, and, rarely, muscle infarcts. Another specific histopathologic finding, albeit a late sign, is perifascicular atrophy. The infiltrates typically have a perivascular distribution. The inflammatory infiltrates are dominated by a high percentage of CD4 T cells and macrophages at the sites of inflammation, with B cells occasionally in evidence. Although perifascicular atrophy is the hallmark of the histologic changes seen in DM, it may not be visible if a biopsy is acquired early in the course of the disease. In early DM, the class I MHC expression is patchy, and the perifascicular areas are usually stained.

The features of PM include the presence of macrophages and activated $CD8^+$ T cells in muscle fibers and the expression of class I MHC molecules on muscle fibers. Mononuclear cell invasion around non-necrotic muscle fibers in endomysial areas is a characteristic feature of PM and IBM. The histologic features of IBM resemble those of PM, but they also include unique features such as red-rimmed vacuoles and inclusions (cytoplasmic or nuclear) and amyloid deposits.[176] An increased number of cytochrome-*c* oxidase–negative fibers can also be seen, but this change is not specific for IBM. In IBM, electron microscopy usually demonstrates 15 to 21 nm cytoplasmic and intranuclear tubulofilaments, which are not found in DM or PM. It is not uncommon to find biopsies that are negative for both rimmed vacuoles and tubulofilamentous inclusions. In this situation, if the suspicion for IBM is high, the diagnosis may be based on typical clinical features. Nonresponsiveness to immunosuppressive treatment further supports the diagnosis of IBM in an otherwise typical patient. Inflammation surrounding necrotic fibers is a feature of some muscular dystrophies (e.g., facioscapulohumeral muscular dystrophy, limb-girdle muscular dystrophy type IIB, Duchenne's muscular dystrophy), in which it is secondary to muscle cell degeneration. The common and unique immunologic and histologic features of the various subgroups are listed in Tables 85-6 and 85-7, respectively.

# IMAGING

## Muscles

Ultrasonography, CT, and MRI are the three general imaging techniques used to evaluate skeletal muscle. MRI has emerged as the method of choice for the examination of soft tissue muscle abnormalities because it efficiently visualizes and quantifies inflammation, fat infiltration, calcification, and alterations in muscle size and localizes pathologic changes to specific muscle groups (Figure 85-11). MRI examinations can be done on large volumes and can be helpful guides for muscle biopsy sampling. MRI is a potential outcome tool to be used in the longitudinal analysis of responses to therapy and in clinical trials, although its sensitivity to changes has not been validated.[209-212]

*Inflammation is absent in a small proportion of polymyositis and dermatomyositis biopsies.
†Also seen in chronic neurogenic conditions and distal myopathies.

Ultrasonography can be used to detect abnormal vascularization, and rates of blood flow can be monitored effectively with color Doppler imaging. The usefulness of ultrasound in diagnosis or as a tool to monitor treatment in patients with IIM still needs to be determined. CT is the modality of choice for identifying calcifications in soft tissues (e.g., JDM), but it is not useful for detecting inflammatory changes in muscle tissue. Cross-sectional CT images allow quantification of muscle atrophy and fat replacement in deep muscles that may not be generally accessible to ultrasonography. A combination of MRI and P-31 MR spectroscopy examinations produces the most comprehensive and accurate evaluation of patients but has not been evaluated for use in clinical practice.[209]

### Lungs

Radiography and high-resolution CT of the lungs are important for detecting lung involvement and should be considered at the time of myositis diagnosis because the prevalence of ILD is high. In contrast, conventional radiography may not always be sensitive enough to detect ILD. These are also important tests for assessing the effects of immunosuppressive treatment.

## ELECTROMYOGRAPHY

Electromyogram (EMG) changes are usually nonspecific but are a useful indicator of myopathic changes. The major abnormalities include abnormal electrical irritability, a decrease in the mean duration of motor unit potentials or increase in the percentage of polyphasic motor unit potentials (short duration), and rapid firing of the motor unit potentials in relation to the level of activity. Later in the course of the disease, fibers are lost from some motor units, and recruitment is reduced. Abnormal electrical irritability in DM and PM involves increased insertional activity, trains of positive sharp waves, and fibrillation potentials. Spontaneous electrical activity is a reasonable measure of disease activity in DM and PM. Earlier studies indicated that EMG abnormalities correlate with alterations in muscle strength and serum muscle enzymes; however, there is an agreement that EMG is not very sensitive to change in muscle strength. The inflammation in IIMs is often patchy, and EMG is useful in determining which muscle should be sampled for biopsy. Because EMG can cause histopathologic changes that complicate the interpretation of the biopsy, it is best to perform EMG on one side and obtain the muscle biopsy from the same muscle on the contralateral side. Even for IBM, in which the disease is often asymmetric, this technique is useful as long as the contralateral muscle is also weak.

## PULMONARY FUNCTION TESTS

Pulmonary function tests are an important means of obtaining an objective assessment of respiratory involvement. Typically, patients demonstrate a restrictive ventilatory impairment, with decreased total lung capacity, functional residual capacity, residual volume, forced expiratory volume in 1 second ($FEV_1$), and forced vital capacity (FVC), but with a normal or elevated $FEV_1$/FVC ratio and reduced diffusing capacity for carbon monoxide. Pulmonary function tests are also important in estimating disease severity and response to therapy, in concert with radiographic examination.

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis of IIMs and other myopathies is important because the clinical associations and response to therapeutic interventions differ significantly. A variety of myopathies closely mimic IIMs (Table 85-8).

### Dystrophic Myopathies

#### Dysferlinopathy

Genetic defects in the dysferlin gene result in limb-girdle muscular dystrophy type 2B and distal muscular dystrophy of the Miyoshi type. These diseases can appear in patients in their late teens or early 20s. The weakness in the limb-girdle type 2B phenotype first assumes a pelvifemoral

**TABLE 85-8** Differential Diagnosis of Inflammatory Myopathies

AST, Aspartate transaminase; CK, creatine kinase; EMG, electromyogram; HIV, human immunodeficiency virus; LDH, lactate dehydrogenase; LGMD, limb-girdle muscular dystrophy.

distribution: the quadriceps muscle is affected first, followed by weakness in the arms in the later stages of the disease. A relatively acute onset with elevated levels of serum muscle enzymes points to PM as a differential diagnosis. The weakness in the Miyoshi phenotype occurs predominantly in the gastrocnemius and soleus muscles, thereby affecting the patient's ability to walk on the toes. The weakness is slowly progressive, with loss of ambulation generally occurring in the fourth decade, but earlier in some cases. Serum CK levels are high during the active phase of the disease. In general, the muscle biopsy is dystrophic, with significant mononuclear cell infiltration and small sarcolemmal defects with thickened basal lamina structures over the defects.[214]

### Facioscapulohumeral Muscular Dystrophy

A partial deletion of the D4Z4 repeats near the chromosome 4q telomere at 4q35 leads to the facioscapulohumeral phenotype. The initial weakness usually affects the facial muscles, and the onset is insidious. Shoulder weakness is commonly seen because of the weakness of the scapular fixator muscles. The weakness is generally slowly progressive, with typical myopathic changes on the EMG such as brief, small-amplitude, polyphonic voluntary motor unit potentials. The presence of perivascular, endomysial, and perimysial inflammation is a common feature.[215] Serum CK levels are elevated and vary with patient age and sex.

### Dystrophinopathies

These X-linked recessive disorders are caused by mutations in the dystrophin gene. Milder forms of Becker's muscular dystrophy manifest as myalgias, muscle cramps, exercise intolerance, mild limb-girdle weakness, and quadriceps myopathy. The severe Becker's phenotype that is seen in patients younger than age 8 years is indistinguishable from the Duchenne's phenotype. An elevation in serum CK levels is seen in asymptomatic patients. In Becker's dystrophy, the number of necrotic and regenerating fibers is decreased when compared with the Duchenne phenotype, and the incidence of hypercontracted and central nuclei increases with age.[216]

### Proximal Myotonic Myopathy

CCTG expansion in intron 1 of the zinc finger transcription factor (ZNF9) gene results in type II myotonic dystrophy. The myotonia usually appears to be absent or minimal but is detectable by EMG. The weakness is mainly proximal, with minimal or no facial involvement. Smooth muscle, cardiac, and diaphragmatic involvement is common in this disease. First-degree heart block is the most common abnormality, and sudden death is well documented.[217] Muscle biopsies show nonspecific features such as central nuclei, sarcoplasmic masses, and atrophy of type I fibers.

### Sarcoglycanopathy

Mutations in sarcoglycans (α, β, γ, and δ) result in limb-girdle muscular dystrophy types IIC to IIF. Sarcoglycanopathies often start in childhood, with a median patient age of onset of 6 to 8 years. These diseases present initially as pelvic muscle weakness, including a waddling gait and difficulty performing common tasks such as getting up from the floor, climbing the stairs, and running. The trunk muscles are prominently affected, and upper extremity involvement usually follows lower extremity involvement. Distal muscles are generally spared until later in the disease process.[218] Dilated cardiomyopathy is often seen in these disorders, and muscle biopsies show marked regeneration and necrosis.

## Neuromuscular Disorders

### Motoneuron Diseases

These diseases, including amyotrophic lateral sclerosis (ALS), are progressive, degenerative disorders of motoneurons in the spinal cord, brain stem, and cerebral motor cortex that manifest clinically as amyotrophy and exaggerated reflexes. These diseases are characterized by a selective loss of function of upper or lower motoneurons, finally leading to a progressive loss of both types of motoneurons over time. EMG shows fibrillation and fasciculation potentials in the muscles of the lower and upper limbs or in the bulbar muscles. Muscle biopsies show the presence of denervation atrophy and secondary myopathic changes in chronically denervated muscles. IBM is the primary muscle disorder most likely to be confused with ALS, and muscle biopsy helps differentiate the two. Serum CK levels are slightly elevated, particularly in the early stages of the disease and in men who are physically active.

### Spinal Muscular Atrophy

Late-onset forms of spinal muscular atrophy (SMA) are characterized by progressive muscle weakness and atrophy and reduced tendon reflexes. EMG and muscle testing reveal neurogenic changes in the muscle. Typical muscle biopsy findings include small and large groups of atrophic fibers in the chronic and severe forms of SMA, respectively. Histochemical changes show fiber type grouping, indicating re-innervation. Serum CK levels are slightly increased in juvenile-onset cases and normal in other forms of SMA. EMG shows abnormal spontaneous electrical activity (fibrillations, positive sharp waves, fasciculations), suggesting ongoing denervation.

### Myasthenia Gravis

The clinical manifestations of myasthenia gravis include abnormal weakness that is worsened by repeated or sustained exertion and fatigability. Proximal muscles are usually more severely affected than are distal muscles. This is a generalized disease that exhibits external ocular muscle involvement, positive anti-cholinesterase drug tests, and a decremental EMG response. Patients are often positive for anti-acetylcholine receptor antibodies.

## Metabolic Myopathies

### Acid Maltase Deficiency

This autosomal recessive glycogen storage disease is caused by acid maltase gene mutations. The disease has infantile,

childhood, and adult variants. The infantile form manifests in the first few months after birth as a rapidly progressive weakness and hypotonia, with death occurring as a result of cardiorespiratory failure. The childhood form manifests as a myopathy in which the weakness is usually greater in the proximal than in the distal muscles; the disease progresses relatively slowly, and patients die of respiratory failure. The adult form presents in the 20s as a progressive myopathy that resembles PM or limb-girdle muscular dystrophy, with additional respiratory symptoms. Serum muscle enzymes (CK, AST, and LDH) are increased in all three forms of the disease, and EMG indicates myopathy in all three cases.

### McArdle's Disease

McArdle's disease is the most common of the nonlysosomal muscle glycogenoses. Exercise intolerance is the characteristic feature of this disease, and it often manifests as early fatigue, myalgia, and stiffness of exercising muscle that is relieved by resting. The EMG is normal in some patients and shows nonspecific myopathic changes in others. Forearm ischemic exercise testing shows virtually no increase in venous lactate in most patients. Serum CK levels, however, are variably elevated in these patients. Muscle biopsies show subsarcolemmal deposits of glycogen at the periphery of the fibers.

## Mitochondrial Myopathies

Mitochondrial diseases are heterogeneous and often present a diagnostic challenge. It has been suggested that myopathy is the result of mutations in mitochondrial DNA in the skeletal muscle.[219] The clinical course of the pure myopathy varies from rapidly progressive to almost reversible disease, with disease onset occurring from infancy through adulthood. The weakness is facioscapulohumeral and more proximal than distal, with involvement of the orbicularis and extraocular muscles. Patients often complain of exercise intolerance and fatigue and have recurrent episodes of myoglobinuria. Muscle biopsy plays a critical role in the diagnosis of these conditions, especially the use of special mitochondrial stains that detect succinate dehydrogenase, Cox staining, and Gomori trichrome staining.

## Endocrine Myopathies

### Cushing's Syndrome

Cushing's syndrome is an endogenous glucocorticoid excess disease that manifests as muscle weakness and wasting. Chronic corticosteroid treatment results in similar manifestations and significant loss of strength within a few weeks of treatment. Muscle biopsy shows increased vacuolations and glycogen accumulation in type II muscle. The onset of weakness is usually insidious. The weakness is primarily proximal, with more severe involvement in the legs than in the arms. These patients generally show normal serum muscle enzyme levels (CK, AST, and LDH). Muscle wasting can often be reversed if the glucocorticoid levels are returned to the normal range.

### Hyperthyroid and Hypothyroid Myopathy

Myopathic thyroid disease is characterized primarily by proximal muscle weakness and muscle wasting. When distal weakness occurs, it often follows proximal myopathy. Exercise intolerance, fatigue, and breathlessness are common complaints, and weakness of the respiratory muscles results in respiratory insufficiency and the need for ventilatory support. Patients often have difficulty rising from a sitting position or lifting their arms above their heads. Serum muscle enzymes (CK, AST, and ALT) are often normal or low in hyperthyroidism and elevated in hypothyroidism. EMG findings are variable, with short-duration motor unit potentials and increased polyphasic potentials in proximal muscles; fibrillations and fasciculations are uncommon.

## Infectious Myopathies

### Human Immunodeficiency Virus Myopathy

Neuromuscular manifestations are common in HIV–induced myopathy. The clinical features typically include a myopathy of subacute onset that progresses slowly. The myopathy often starts as proximal symmetric muscle weakness with or without muscle wasting, similar to that in IIMs. EMG shows spontaneous activity, with fibrillation potentials, positive sharp waves, and brief, low-amplitude polyphasic motor unit potentials.

### Human T-Lymphotropic Virus I Myopathy

Myositis associated with human T-lymphotropic virus I (HTLV-I) has been noted in certain areas of the world (e.g., Japan, Jamaica). In these patients, symptoms of PM and IBM occur either alone or in combination with tropical spastic paraparesis.[220] Typical features include weakness and increases in serum CK levels. Histologic findings include interstitial inflammation, muscle fiber necrosis in PM and endomysial inflammation, vacuoles, amyloid deposits, and tubulofilaments in IBM.

## Parasitic Myopathies

Diseases caused by various parasites—protozoa (e.g., toxoplasmosis, trypanosomiasis, sarcocystosis, malaria), cestodes (e.g., cysticercosis, echinococcosis, coenurosis, sparganosis), and nematodes (trichinellosis, toxocariasis, dracunculiasis)—can cause myositis. The clinical features include nonspecific complaints such as myalgia and focal swelling, as well as typical features of PM and DM. Each parasitic infection shows typical changes on muscle biopsy (e.g., the presence of tachyzoites and toxoplasma cysts along with perimysial and endomysial inflammation). A combination of muscle biopsy and serologic findings is useful in making a diagnosis.

## Drug-Induced Myopathies

D-penicillamine is known to induce clinical features reminiscent of DM. Recovery usually occurs after withdrawal of the drug. Agents such as IFN-α that are used to treat viral hepatitis and certain malignant tumors are also known to

induce clinical features that resemble PM. Amphiphilic drugs such as chloroquine, hydroxychloroquine, and amiodarone are also known to induce cytoplasmic vacuoles, necrosis, and longitudinal branching of muscle fibers.[221] Drugs that affect microtubules, such as colchicine and vincristine, also induce myopathic changes, with the appearance of characteristic autophagic vacuoles in muscle fibers. Nucleoside analogues such as zidovudine are used to treat HIV because they act as false substrates for the viral reverse transcriptase. These drugs also cause myalgias, proximal muscle weakness, and fatigue and are sometimes associated with increased levels of serum CK. In these patients, zidovudine-induced mitochondrial myopathy may coexist along with HIV-induced T cell–mediated inflammatory myopathy.[222]

## MANAGEMENT AND OUTCOME

The recommended treatment for patients with PM or DM is based on a combination of pharmacologic therapy and physical exercise. The optimal pharmacologic treatment in PM and DM is unclear. Few controlled trials have been undertaken, so recommendations are based on clinical observations from case series. With these limitations in mind, a suggested outline of treatment for patients with PM or DM is depicted in Figure 85-12. In addition to providing treatment, it is important to give patients adequate information about their disease and its treatment. This educational component is best provided by a rheumatology team and patient support groups.

### Pharmacologic Treatment

The initial pharmacologic treatment in PM and DM is high-dose glucocorticoids: 0.75 to 1 (as much as 2) mg/kg body weight per day of prednisone for 4 to 12 weeks. Most experts recommend that glucocorticoid treatment be combined with another immunosuppressive drug to reduce the side effects of the glucocorticoid and to boost the immunosuppressive effect. The most frequently used

immunosuppressive agents are azathioprine and methotrexate. In the extension phase of one of the few double-blind, placebo-controlled trials that have been reported, the combination of azathioprine and glucocorticoids, as compared with prednisone alone, was associated with better functional ability and a lower requirement for prednisone after 1 and 3 years.[223,224] The recommended azathioprine dosage is 2 mg/kg per day. The dosing regimen for methotrexate is similar to that for rheumatoid arthritis—as much as 25 mg weekly, although there have been reports of higher doses. Pulmonary involvement related to myositis does not seem to be a contraindication for methotrexate.

The combination of methotrexate and azathioprine has proved to be successful in a few patients with refractory myositis in a prospective, randomized, open-label crossover study comparing two aggressive approaches. There are also newer reports that mycophenolate mofetil might be effective. In patients with ILD, cyclophosphamide could be of value. There are also a few reports that cyclosporine A or tacrolimus can be beneficial in these cases.[225,226] In treatment-resistant DM, a high dose of IVIG had a beneficial effect on muscle strength when compared with placebo; however, the therapeutic effect was temporary, and repeated infusions were required.[227] In patients with severe, rapidly progressive disease that might be life threatening, high-dose pulses of IV methylprednisolone have been reported to be beneficial. Pharmacologic treatment, including tapering of the corticosteroid dose, should be guided by clinical outcome measures. As discussed earlier, the most appropriate outcome measures are muscle endurance and muscle strength. Side effects of glucocorticoids in these high doses are frequent. Prophylaxis against osteoporosis is recommended with vitamin D and calcium and, when clinically indicated, bisphosphonates. Steroid myopathy is another possible consequence of glucocorticoid treatment that is particularly problematic in patients with inflammatory myopathies. There is no specific test to verify steroid myopathy, but in the absence of active clinical disease, steroid myopathy could contribute to muscle weakness. If steroid myopathy is suspected, tapering of the glucocorticoid dose with careful evaluation of the clinical response is recommended. Glucocorticoids may also cause hypokalemia, and if this is not corrected, it may be associated with muscle weakness and incorrectly interpreted as myositis activity. The depletion of B cells has recently emerged as a new strategy in autoimmune diseases. One approach is to use rituximab (monoclonal antibody against CD20). Although a large multicenter randomized clinical trial (RIM trial) in patients with refractory PM, DM, and JDM did not meet its endpoint, a post hoc analysis of the RIM trial indicate that presence of anti-Jo-1 or anti-Mi-2 autoantibodies may predict response to rituximab.[228,229,230] Use of TNF inhibitors has produced mixed results. For example, treatment with infliximab at 3 mg/kg resulted in improved muscle function in patients with juvenile DM. However, interpretation of the data from this trial was complicated by the fact that all of the patients were concomitantly treated with a tapering dose of prednisone.[231] A second, larger trial examining the use of infliximab in patients with PM, DM, or IBM found that only 30% of patients experienced an improvement in disease symptoms, whereas the remaining participants suffered from adverse side effects or worsening of the disease.[232] In addition, a pilot study of etanercept showed worsening of the rash associated with DM.[233]

IBM is usually nonresponsive to glucocorticoids. There are occasional case reports of "stabilization" for a period of months, but this condition probably reflects the natural history of the disease. Prolonged administration of glucocorticoids to patients with IBM may actually lead to worsening of clinical aspects of the disease, despite the improvement in CK levels and reduced T cell numbers in biopsies. Prednisone treatment also increases the number of amyloid-containing fibers.

A few small studies have shown some beneficial effect of methotrexate, anti–T lymphocyte globulin, or mycophenolate. However, an open-label trial comparing methotrexate with methotrexate with anti-T lymphocyte globulin showed deterioration in the methotrexate group.[234]

Anabolic steroids and oxandrolone may have some beneficial effects on muscle strength, although this benefit needs to be confirmed in larger studies. Most experts consider their use justified in combination with glucocorticoids for a limited period in patients who have inflammatory infiltrates on muscle biopsy, or in combination with a more aggressive immunosuppressive treatment (e.g., methotrexate, azathioprine) in patients with another connective tissue disease. Treatment of JDM is similar to adult IMM. (For details, please see the JDM clinical section.)

## Nonpharmacologic Treatment

With immunosuppressive treatment, approximately 75% of all patients improve, but few recover normal muscle function, even in the absence of muscle inflammation. In previous decades, patients with myositis were advised against exercise because of concerns over possible muscle damage and inflammation, but recent publications have demonstrated that combining exercise and immunosuppressive therapy is a safe approach and has clear beneficial effects on muscle strength and function.[235] Chronic inflammation leads to loss of skeletal muscle because of low levels of physical activity, negative effects of glucocorticoids, and circulating cytokines. In addition, in late phases of disease, patients with PM and DM may still experience muscle weakness, despite absence of muscle inflammation.[128] Exercise has proven safe and able to improve muscle performance and health-related quality of life in both early and late phase of disease. Emerging evidence suggests that exercise can even decrease muscle and systemic inflammation.[236] Similar to healthy individuals, exercise has a short-term benefit and needs to be implemented on a regular basis.[237-241]

In a pair of small studies of immunosuppressed myositis patients, personalized submaximal exercise programs improved[237] muscle function without causing any increase in inflammation. This improvement was true for patients who had individually tailored exercise regimens[242] and self-administered home exercise routines.[243] Examinations of biopsies both before and after exercise indicated that the patients showed improved muscle strength as the result of an increase in the proportion of slow twitch (type I) muscle fibers and a reduction in inflammation and fibrosis.[243,244] More evidence suggests that combining exercise and immunosuppressive therapy is a safe approach and can improve

performance without disease exacerbation, and exercise can decrease muscle and systemic inflammation.[231,245] The exercise regimen should be individualized and supervised by a physiotherapist to avoid the overuse of muscles, and it should combine aerobic and resistance exercise, starting approximately 4 weeks after initiation of immunosuppression.[237] Physical exercise is now recommended as a combination therapy with immunosuppressive treatment.

## Assessing Disease Activity and Outcome

The most important variable to measure in myositis patients is muscle performance or physical function. However, it is equally important to evaluate whether impaired muscle function reflects disease activity or irreversible muscle damage.

### Muscle Examination

**Manual Muscle Test.** There are several tools to measure muscle performance, but the method used most often in clinical practice and clinical trials is the manual muscle test with the MRC scale (see earlier). The drawback is that these tools measure muscle strength but not muscle endurance, which is often a major problem in PM or DM. Furthermore, they have not been validated in adults with inflammatory myopathies. Previously, the number of muscle groups tested using the manual muscle test varied, and different scales were used (5 or 10 grade). Recently, a consensus was reached to assess eight muscle groups on the dominant side using a 0- to 10-point scale, in which 0 indicates no muscle contraction, 5 indicates the ability to hold the test position without any added pressure, and 10 indicates the ability to hold the test position against strong pressure. The points between these scores are based on gradual increased resistance against the examiner's pressure. The eight muscle groups tested are neck flexors, shoulder abduction (deltoid middle), biceps brachii, wrist extensors, knee extensors (quadriceps), dorsiflexion of ankle, gluteus maximus, and gluteus medius. The score achieved varies between 0 and 80.

**Functional Index in Myositis.** The Functional Index in Myositis and its revised form, the Functional Index in Myositis-2, were developed as outcome measures for patients with PM or DM. This test measures the number of repetitions that can be performed in defined muscle groups.[194,199] It is a more sensitive method of measuring impaired muscle function in patients with PM or DM.[194] The drawback is that it takes longer to perform than the manual muscle test, and it may be difficult to use in everyday clinical practice. Preferably, the Functional Index in Myositis-2 is administered by a physiotherapist and can be combined with the manual muscle test.

### Extramuscular Involvement

In some patients, extramuscular symptoms predominate among the clinical features. These symptoms may require other assessment tools, such as those used to evaluate ILD. For monitoring the effects of treatment of ILD, high-resolution CT and pulmonary function tests are recommended.

**TABLE 85-9** Disease Activity Measure: Core Set

| |
|---|
| Physician's overall assessment of disease activity on a visual analogue scale (VAS) |
| Patient's or parent's overall assessment of disease activity (VAS) |
| Functional assessment (health assessment questionnaire) |
| Muscle strength testing (manual muscle test) |
| Serum levels of at least 2 of 4 muscle enzymes (CK, LDH, AST, ALT) |
| Extramuscular score (myositis disease activity assessment VAS [MYOACT] or myositis intention to treat activity index [MITAX]), in which disease activity in seven organ systems (general symptoms, skin, joints, gastrointestinal tract, pulmonary, heart, and muscles) is scored |

ALT, Alanine transaminase; AST, aspartate transaminase; CK, creatine kinase; LDH, lactate dehydrogenase.

### Disease Activity and Damage

It is also important to distinguish whether symptoms are caused by active inflammatory disease or are a consequence of organ damage. IMACS, an international collaboration, made a consensus recommendation that outcome measures for patients with myositis include tools that measure disease activity, damage, and health related quality of life. The IMACS network has developed one outcome measure to assess myositis disease activity and one to measure organ damage: the myositis disease activity assessment tool and the myositis damage index, respectively.[193] The disease activity outcome measure is a core set that consists of the six variables listed in Table 85-9. The damage index is recorded by the physician on the basis of the patient's history and covers several organ systems that can be affected in patients with inflammatory myopathies. To assess the impact on general health, the generic Short Form 36, a self-administered health-related quality of life questionnaire, is recommended. These outcome measures have been developed for clinical trials and research but can also be useful in clinical practice. More detailed information about these outcome measures can be found on the IMACS website: https://dir-apps.niehs.nih.gov/imacs.

IMACS has also reached a consensus on what constitutes improvement. Improvement is based on the disease activity core set and is defined as greater than 20% improvement in three of the six variables of the core set, with two or fewer of the variables (except the manual muscle test) worsening by less than 25%. However, this definition of improvement must be validated in longitudinal studies.

CHAPTER 86

# Overlap Syndromes

Robert M. Bennett

**KEY POINTS**

- In their early stages most autoimmune connective tissue diseases (AICTD) are not clinically well differentiated; this stage of their evolution is called undifferentiated connective tissue disease (UCTD).
- About 50% of UCTDs remain undifferentiated.
- Important clues as to the eventual direction of differentiation can be obtained from nailfold capillary microscopy and the autoantibody profile in conjunction with regular clinical evaluations.
- All of the major AICTDs have varying degrees of overlap with each other; the propensity for this overlap is often correlated with a distinctive autoantibody profile.
- Mixed connective tissue disease (MCTD) is the prototypical overlap disease with features of lupus, rheumatoid arthritis, scleroderma, and inflammatory myositis. This overlap is not seen at the outset of MCTD; rather it often takes several years to develop.
- The most common presentation of MCTD is Raynaud's phenomenon.
- MCTD is most commonly associated with antibodies to U1-RNP; in general this antibody predicts lack of severe renal and CNS involvement.
- The major cause of death in MCTD is pulmonary hypertension, and all MCTD patients should have regular echocardiograms to determine its evolution.
- The management of overlap syndromes is based on the usual treatment of the constituent features of its clinical components (i.e., systemic lupus erythematosus, rheumatoid arthritis, scleroderma, and inflammatory muscle disease).

The clustering of symptoms and signs into readily recognizable groupings has an important historic precedence in the classification of disease. With the progress of knowledge, such groupings may become more precisely defined in terms of distinctive pathology, specific laboratory findings, and genetic associations. According to current nosology, there are six autoimmune connective tissue diseases (AICTDs):

- Systemic lupus erythematosus (SLE)
- Scleroderma (Scl)
- Polymyositis (PM)
- Dermatomyositis (DM)
- Rheumatoid arthritis (RA)
- Sjögren's syndrome

All six classic AICTDs are descriptive syndromes without a "gold standard" for diagnosis. The diagnosis of a diffuse connective tissue disorder (DCTD) is usually readily apparent without recourse to extensive investigations. However, in the early stages there are often common features such as Raynaud's phenomenon, arthralgias, myalgias, esophageal dysfunction, and positive tests for anti-nuclear antibodies (ANA). In such cases, the diagnosis is not always so obvious. These cases are often referred to as *undifferentiated connective tissue disease* (UCTD).[1] Approximately 35% of such patients have clinical overlap syndromes. whereas most differentiate into a clinical picture consistent with the traditional description of a DCTD. In some instances, one DCTD evolves into another DCTD with time.

The propensity for differentiation into a classic DCTD or the maintenance of an overlap state is often associated with distinctive serologic profiles and major histocompatibility (MHC) linkages. Although most rheumatologists generally feel more comfortable thinking in terms of the classic DCTD paradigms, a case can be advanced for the use of serologic profiles and human leukocyte antigen (HLA) typing to better understand the clinical features and prognoses. In this respect, a careful analysis of the overlap syndromes and their serologic associations has provided insights to understand the clinical heterogeneity of the AICTDs.[2] Numerous clinical correlations of autoantibodies have been reported and are summarized in Table 86-1.

## EPIDEMIOLOGY

The reported prevalence of AICTDs is variable and depends on the study methodology, nature of referral bias, and patient ethnicity.[3]. It is generally accepted that Sjögren's syndrome has the highest prevalence (0.5% to 3.6%), whereas SLE has a much lower prevalence of approximately 15 to 50 cases per 100,000 individuals. Scl, PM, and DM are relatively rare AICTDs, with a prevalence of less than 10 per 100,000 individuals. There is increasing realization that overlap syndromes of Scl and myositis are more common than the "pure" forms of the disease.[4] Two epidemiology studies examined the prevalence of mixed connective tissue disease (MCTD). In Japan, the point prevalence was 2.7 per 100,000,[5] and in Norway it was 3.8 per 100,000, with a yearly incidence of 2.1 per million.[6] The syndrome of MCTD usually occurs as an isolated finding, but there are reports of a familial occurrence. Unlike SLE, precipitation by sun exposure has not been described in patients with MCTD. Similarly, drug exposure has not been related to the onset of MCTD, although a transient appearance of antiribonuclear protein (RNP) antibodies has been seen at the initiation of procainamide therapy.[7] Vinyl chloride and

**TABLE 86-1** Correlations of Autoantibodies with Clinical Features

| Autoantigen | Clinical Associations |
|---|---|
| ACL/B2-glycoprotein | SLE, thrombosis, thrombocytopenia, miscarriages |
| Alpha enolase | Behçet's disease, RA, MCTD, Scl, Takayasu's |
| Angiotensin-converting enzyme 2 | AICTDs with vasculopathy |
| Anti-TIF1 (anti-p155/140) | Dermatomyositis and cancer |
| B2-glycoprotein independent ACL | MCTD (not associated with APL syndrome) |
| Centromere | Limited Scl, CREST, Raynaud's phenomenon, pulmonary hypertension, PBC |
| Citrullinated peptides | Rheumatoid arthritis |
| dsDNA | SLE, glomerulonephritis, vasculitis |
| Endothelial cell | Pulmonary hypertension, severe digital gangrene |
| Fibrillarin | Severe generalized Scl |
| Fodrin | Sjögren's syndrome, glaucoma, Moyamoya disease |
| Histones H1, H2A, H2B,H3, H4 | SLE, UCTD, RA, PBC, generalized morphea |
| hnRNP-A2 (also called RA-33) | MCTD, RA, erosive arthritis in SLE and Scl |
| hnRNP-I | Scl (early diffuse and limited) |
| Ku | Myositis overlap, primary pulmonary hypertension, Grave's disease |
| Malondialdehyde 5 5 | Amyopathic dermatomyositis and progressive lung disease |
| Myeloperoxidase | Eosinophilic granulomatosis with polyangiitis (Churg-Strauss Syndrome), pauci-immune glomerulonephritis |
| Nucleosome | SLE, Scl, MCTD |
| Platelet-derived growth factor (PDGF) | Diffuse and limited Scl |
| PM / Scl | Myositis overlap with arthritis, skin lesions, mechanic's hands |
| Proteasome | SLE, PM/DM, Sjögren's syndrome, multiple sclerosis |
| Proteins 3 | GPA, pulmonary capillaritis |
| Rheumatoid factor | RA, erosive arthritis, cryoglobulinemia, other systemic autoimmune diseases |
| Ribosomal P | Psychosis in SLE |
| RNA polymerases I and III | Scl (diffuse with renovascular hypertension.) |
| Ro/La | Sjögren's syndrome, SLE, congenital heart block, photosensitivity, PBC |
| Signal recognition particle—SRP | Myositis overlap (severe course with cardiac disease) |
| Sm snRNP | SLE |
| Synthetases (Jo-1, PL-7, PL-12) | Myositis overlap with arthritis and interstitial lung disease |
| Th/To | Limited Scl |
| Topoisomerase 1 (Scl-70) | Diffuse Scl with prominent organ involvement |
| U1 snRNP | MCTD, SLE, PM |
| U1-RNP (68 kDa peptide) | MCTD, Raynaud's phenomenon, pulmonary hypertension |
| U3 snRNP | Limited Scl |
| U5 snRNP | Myositis overlap |

AICTD, Autoimmune connective tissue diseases; APL, anti-phospholipid antibody; CREST, calcinosis, Raynaud's phenomena, esophageal dysmotility, sclerodactyly, and telangiectasia; DM, dermatomyositis; GPA, granulomatosis with polyangiitis; MCTD, mixed connective tissue disease; PBC, primary biliary cirrhosis; PM, polymyositis; RA, rheumatoid arthritis; ScL, scleroderma; SLE, systemic lupus erythematosus; UCTD, undifferentiated connective tissue disease.

silica are the only environmental agents associated thus far with MCTD.

## AUTOIMMUNITY IN OVERLAP SYNDROMES

Gene expression is mediated by a cascade of RNA functions that regulate, process, store, transport, and translate RNA transcripts. The RNA network that promotes this cascade depends on a large cohort of proteins that partner RNAs: so-called *ribonucleoproteins* (RNPs). Because the cytosol and nucleoplasm need to be densely packed (with its severe restriction on diffusion of macromolecules), partitioning of the eukaryote cell into functionally specialized compartments is essential for efficiency. This necessitates the association of RNA and protein into large RNP complexes, including ribosomes and spliceosomes.[8] There is compelling evidence that autoimmunity is often antigen driven by these RNA-associated components of subcellular particles.[6]

## Autoimmunity to Spliceosomal Components

Certain components of the spliceosome are common targets of autoimmunity in the AICTDs.[9] Furthermore, it appears that post-translational modifications of these molecules, as occurs during apoptosis, are often associated with increased immunogenicity.[10] Spliceosomes are complex nuclear particles made up of some 300 distinct proteins and five RNAs, which are involved in the processing of premessenger RNA into mature "spliced RNA."[11] Two major spliceosomal subunits are antigenic targets in autoimmunity: small nuclear ribonucleoprotein protein particles (snRNP) and heterogeneous nuclear RNP particles (hnRNP).

The snRNPs contain small RNA species ranging in size from 80 to 350 nucleotides, which are complexed with proteins.[12] These RNAs contain a high content of uridine, and are therefore called *U-RNAs*; five different U-RNAs were defined on the basis of immunoprecipitation (U1, U2, U4, U5, and U6). Autoantibodies to these complexes are mainly directed to the protein components. Anti-Sm antibodies precipitate five proteins with molecular weights of 28,000 (B'B), 16,000 (D), 13,000 (E), 12,000 (F) and 11,000 (G); five of these polypeptides are common to the U1-, U2-, U4-, U5-, and U6-RNAs. Anti-RNP antibodies precipitate three proteins with molecular weights of 68,000 (70K), 33,000 (A'), and 22,000 (C); these polypeptides are uniquely associated with U1-RNA (Figure 86-1). The clinical correlates distinctive of MCTD are associated with the 70 kDa specificity with an immunodominant epitope-embracing amino acid residue 125 flanked by important conformational residues at positions 119-126. On the other hand, SLE is associated with anti-Sm antibodies.

The heterogeneous nuclear RNP particles (hnRNP) are among the most abundant proteins in the eukaryotic cell nucleus. They contain pre-mRNA associated with 30 small proteins that are all structurally related and have molecular weights of 33 to 43 kDa. Nine hnRNP core proteins have been designated A1, A2, B1a, B1b, B1c, B2, C1, C2, and C3. An antibody termed *anti-RA33*, which targets the 33 kDa hnRNP-A2, is particularly interesting. It is found in approximately one third of sera from patients with RA, SLE, and MCTD.[13] Furthermore, it has associations with patient subsets of erosive arthritis in SLE, Scl, and MCTD, and predicts the eventual development of RA in patients with early polyarthritis.[14] Importantly, this association with anti-RA33 is not seen in Scl (sine erosions), PM, or overlaps of PM/Scl or PM/DM. The antigenic epitopes of hnRNP-A2 contain two RNA-binding regions at the N-terminal end and a glycine rich C-terminal region. Certain disease subsets target these two RNA-binding regions differently. For instance, RA and SLE sera preferentially react with the complete second RNA-binding domain, whereas MCTD sera target an epitope that spans both RNA-binding domains.

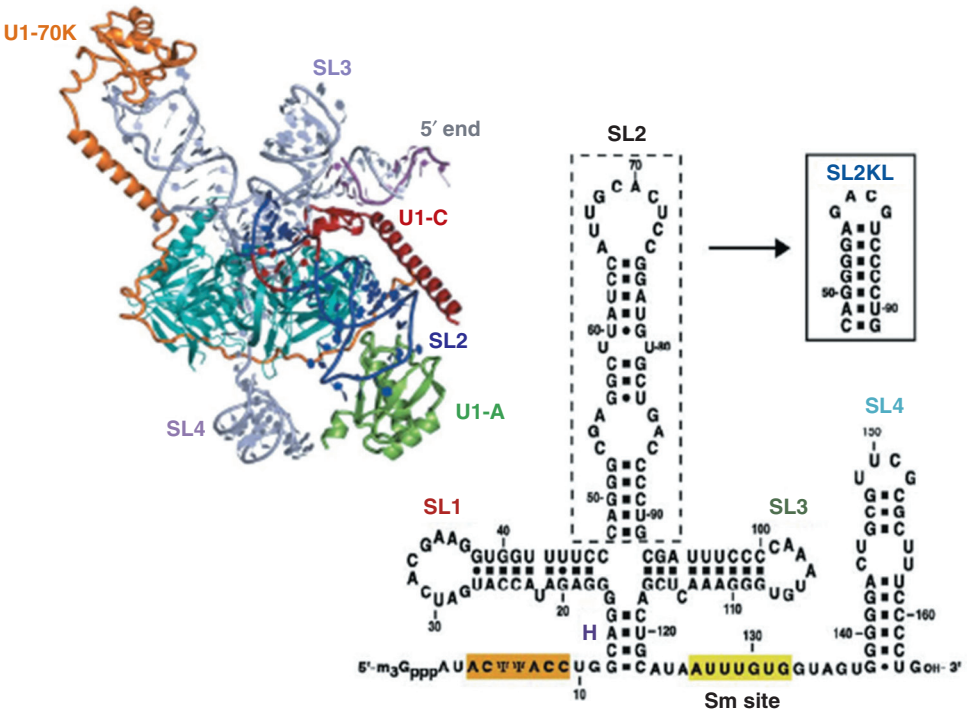

**Figure 86-1** Anatomy of the spliceosome. The spliceosome is made up of five small nuclear RNAs (snRNAs) complexed with proteins to form a small nuclear ribonucleoprotein particle (snRNP). This subcellular structure is responsible for splicing introns from pre-mRNA to form mRNA via a 59-splice recognition site. Antibodies to various spliceosomal constituents are a common feature of autoimmune rheumatic disorders with a tendency to associate with different clinical profiles (see Table 86-1). The U1 small nuclear RNP (U1 snRNP) particle of the spliceosome is composed of U1 RNA, RNP proteins (70 kDa, A, and C), and common Sm proteins (B'B, D, E, F, and G). The structure of U1 RNA consists of single-stranded RNA and double-stranded RNA called stem-loops I, II, III, and IV. An electron density map of the functional core of U1 snRNP at 5.5 A resolution has enabled the spatial visualization of the RNA and placement of the seven Sm proteins, U1-C, and U1-70K into the map. A striking feature is the amino (N)-terminal polypeptide of U1-70K, which extends over a distance of 180 A from its RNA-binding domain, wraps around the core domain consisting of the seven Sm proteins, and finally contacts U1-C, which is crucial for 59-splice-site recognition. *(Modified from Newman J: Structural studies of the spliceosome.* Curr Opin Struct Biol *20:82-89, 2010; and Pomeranz AD: Crystal structure of human spliceosomal U1 snRNP at 5.5 A resolution.* Nature *458:457-480, 2009.)*

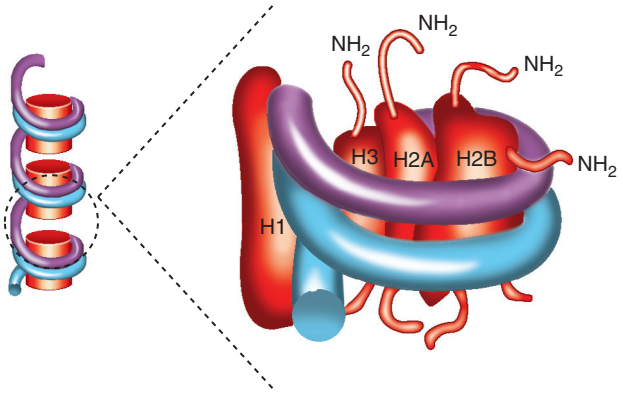

**Figure 86-2** Anatomy of the nucleosome. The nucleosome is the fundamental repeating unit of chromatin. The central part of the nucleosome is composed of a tetramer composed of two molecules of histones H3 and H4, flanked by two dimers of histones H2A and H2B. This central core is surrounded by two super-helical turns, consisting of 146 base pairs of histone-free DNA. Histone H1 is located at the point where DNA enters and exits the nucleosome. Antibodies to the nucleosome arise early in the evolution of systemic lupus erythematosus—before anti-DNA and anti-histone antibodies. Thus, the nucleosome is thought an important early autoantigen in the development of epitope spreading. Nucleosome antibodies are also found in scleroderma and mixed connective tissue disease. *(From Amoura Z, Koutouzov S, Piette C, et al: The role of nucleosomes in lupus.* Curr Opin Rheumatol *12:369-373, 2000.)*

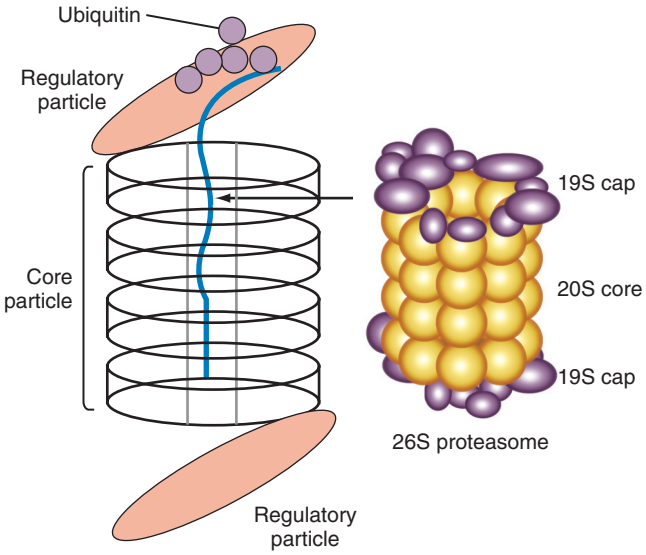

**Figure 86-3** Anatomy of the proteasome. Most proteins in the cytosol and nucleus are degraded via the proteasome-ubiquitin pathway. The 26S proteasome is a huge complex of 2.5 mega-dalton size, made up of approximately 35 different subunits. It contains a proteolytic core complex, the 20S proteasome, and one or two 19S regulatory complexes that associate with the termini of the barrel-shaped 20S core. The function of proteasomes is twofold: (1) to degrade intra-cellular proteins that have been tagged with ubiquitin, and (2) to generate antigenic peptides for presentation by the class I major histocompatibility complex molecules. Antibodies to proteasomal subunits have been reported in several autoimmune diseases (especially systemic lupus erythematosus and polymyositis/dermatomyositis) and elevated levels of proteasomes have been correlated with disease activity.

## Autoimmunity to Nucleosomal Components

Nucleosomes are the compact building blocks of chromatin and consist of an octamer of two copies of histones H2A, H2B, H3, and H4, wrapped around approximately 146 base pairs (bp) of DNA (Figure 86-2). During apoptosis, endonucleases cleave chromatin with the liberation of nucleosomal particles. Following the release into the cytoplasm, nucleosomes migrate to the surface of the dying cell[15] and thus become accessible to B cell receptors. The development of autoimmunity has been linked to defective phagocytosis of apoptotically released constituents.[15] Nucleosomal antibodies are directed to antigenic determinants on the intact nucleosome rather than its individual components, DNA, and histones. In a study of 496 patients with 13 different DCTD, and 100 patients with hepatitis C, antinucleosome antibodies were found in the sera of patients with SLE (71.7%), Scl (45.9%), and MCTD (45.0%).[16]

## Autoimmunity to Proteasomal Components

The 26S proteasome is a large subcellular particle involved in the degradation of proteins that have been tagged with ubiquitin, and the generation peptides for presentation by the class I MHC molecules (Figure 86-3). There is good evidence that it is the target of an autoimmune response in DCTD. Antibodies to proteasomal subunits have been reported in patients with autoimmune myositis, SLE, and primary Sjögren's syndrome. Circulating 20S proteasomes (c20S) subunits appear to have an association with disease activity in MCTD and SLE.[17]

## Generation of Autoimmunity

The antibody response to just one component of an intracellular structure, such as a spliceosome, will result in the uptake of the entire particle by antigen processing cells (APC). Thus all the proteins that make up the particle will be subject to antigen processing, with potential peptide presentation linked to their affinity to class II HLA antigens. Depending upon the polymorphisms of the individuals HLA molecules, there will be a diversification of the antibody response to include some of these other antigens. This process is called *epitope spreading* and is considered pivotal in the development of the linked antibody responses that are observed in different CTDs.[18] For instance, the induction of an immune response to one component of a U-RNP complex can induce a diversified auto-antibody response to other components of the complex.[19] In this way an immune response becomes modified with time, and this change has been associated with changes in the clinical picture.

The interaction of T cell receptors (TCRs) and peptides presented by HLA molecules are a critical event in the generation of autoimmunity. The 70 kDa anti-U1 RNP antibody responses are associated with the HLA DR4 and DR2 phenotype.[20] DNA sequencing of HLA-DB genes has revealed that DR2- and DR4-positive patients share a common set of amino acids in the beta chain at positions 26, 28, 30, 31, 32, 70, and 73, which form a pocket for antigen binding. It is hypothesized that these two HLA subtypes represent a critical genetic specificity for the presentation of antigenic peptides to their cognate T cell receptors.[21] The shared epitope on HLA-DR4/DR2 that is associated with an anti-U1-RNP response is different from the shared epitope associated with HLA-DR4/DR1 in RA patients.[22] The 70 kDa polypeptide has several different

epitopes. The most consistent sequence is KDK DRD RKR RSS RSR.[23] This region is preferentially targeted by MCTD sera, but not by SLE sera.[24] The autoimmune response to the spliceosome in these three disorders is characterized by differential degrees of epitope spreading. The widest range of antibodies, to both snRNP and hnRNP, is seen in SLE, a more restricted antispliceosomal antibody repertoire to snRNP and hnRNP is seen in MCTD, and in RA the antispliceosomal antibody repertoire is restricted to hnRNP.[25] In general, the autoimmune rheumatic diseases are characterized by the production of autoantibodies that recognize evolutionarily conserved molecules. The two main theories are apoptotic modification[26] and molecular mimicry.[27] Proteins modified during apoptosis can be presented to the immune system in ways that bypass tolerance to self-proteins.[12] Although rheumatic disease autoantigens are not unified by a common structure or function, they do have the common feature of becoming clustered and concentrated as blebs the surface of apoptotic cells. A population of small blebs contains fragmented endoplasmic reticulum and ribosomes, as well as the ribonucleoprotein Ro. A larger population of surface blebs contains nucleosomal DNA, Ro, La, and the small nuclear ribonucleoproteins.[28] During the process of apoptosis, several enzyme systems are up-regulated with resulting post-translational modifications of the cleaved proteins. These modifications, which include citrullination, phosphorylation, dephosphorylation, transglutamination, and conjugation to ubiquitin, render the molecules more antigenic. For instance, the U1-70K protein is cleaved by the enzyme caspase-3, converting it into a C-terminally truncated fragment that contains a major B cell epitope that is preferentially recognized by autoimmune sera.[29]

The initial stimulus for a first antibody response may be a non-self-protein possessing a peptide region that mimics a self-epitope: a so-called "molecular mimicry". Environmental stressors such as infection, toxins, drugs, and ultraviolet light may, under some circumstances, induce accelerated apoptosis. A critical limitation to molecular mimicry is the necessity for the antigenic sequence to undergo TCR recognition. T helper (Th) lymphocytes ($CD4^+$) usually recognize peptides of 12-16 amino acids in the context of class II HLA molecules. However, in some instances, smaller peptides may be recognized, which are more immunostimulatory than the parent ligand. Thus antigen recognition by T cells is highly degenerate and expands the potential for molecular mimicry because the universe of molecules containing a pentapeptide, for example, is many-fold greater than for 12 amino residue peptide. Once an immune response to one component of an immunogenic molecular complex has been elicited, other proteins/epitopes of the complex may become antigenic by the same process of epitope spreading.[18]

## Regulation of Autoimmunity

**KEY POINTS**

**Most patients with a UCTD have Raynaud's phenomenon in combination with unexplained arthralgias.**

**Approximately 35% of patients with a UCTD eventually manifested a defined CTD within 5 years**

**Nailfold capillary microscopy is useful in evaluating the potential for evolution into a defined CTD.**

**An increase in the ratio of Th17 cells to Tregs predicts the differentiation into a defined CTD.**

Once an autoimmune reaction becomes established, a counter-offensive is mounted by immuno-regulatory T cells (Tregs).[30] These cells, characterized by the presence of CD4, CD25, and Foxp3, develop in the thymus and are called *naturally occurring Tregs*. Another population of regulatory T cells develops in the periphery, and these are called *induced regulatory T cells* (iTregs); these are characterized by the presence of $CD4^+$ $CD25^+$ $Foxp3^+$ and the production of IL-10. In many autoimmune disorders, Th17 cells are pivotal in the initiation of the inflammatory response and tissue destruction. Th17 cells produce IL-17, which causes activation and migration of neutrophils; they also secrete IL-21 and IL-22. Lack of Th17 cells is associated with opportunistic infections. The ratio of Th17 cells to Tregs is commonly used as a marker of disease intensity or susceptibility to developing an autoimmune disorder (Figure 86-4).

## UNDIFFERENTIATED CONNECTIVE TISSUE DISEASE

Rheumatologists frequently see patients with a weakly positive ANA and nonspecific symptoms such as arthralgias, fatigue, and cold sensitivity. The critical questions for such patients are "will they develop a connective tissue disease?" or "do they have fibromyalgia?" The answer to these questions is not always straightforward because fibromyalgia is not a diagnosis of exclusion.[31] It has a common comorbidity with the well-defined CTDs, and is often associated with cold-induced vasospasm.[32] An algorithm for diagnosing UCTDs is given in Figure 86-5. In the early stages of a CTD, there may be just one or two suspicious clinical and laboratory features, but a definitive diagnosis cannot always be made. In such cases a working diagnosis of UCTD may be appropriate.[33] Most patients with this UCTD have Raynaud's phenomena with or without an unexplained polyarthralgia, and a positive ANA with usually just a single autoantibody specificity, often anti-Ro and anti-RNP.[34] A 5-year follow-up study of 665 patients with UCTD reported a well-defined CTD (RA, 13.1%; Sjögren's syndrome, 6.8%; SLE, 4.2%; MCTD, 4.0%; Scl, 2.8%; systemic vasculitis, 3.3%; and PM/DM 0.5%) developed in only 34% of patients.[35] Certain combinations of features are predictive for the development of an established CTD: polyarthritis plus U1RNP antibodies predict MCTD, sicca symptoms plus anti–SS-A/SS-B antibodies predict Sjögren's syndrome, Raynaud's phenomenon plus a nucleolar ANA pattern predict Scl, polyarthritis plus high levels of rheumatoid factor predict RA and fever/serositis plus a homogeneous ANA pattern or anti-dsDNA antibodies predict progression into SLE (Table 86-2). In a follow-up study of 104 patients presenting with isolated Raynaud's phenomena, the presence of giant loops on capillaroscopy was a significant prognostic factor for the development of Scl with a hazard ratio of 2.64 (Figure 86-6).[36]

A shift in the balance between Th17 cells and Tregs is an important feature in the development of autoimmune

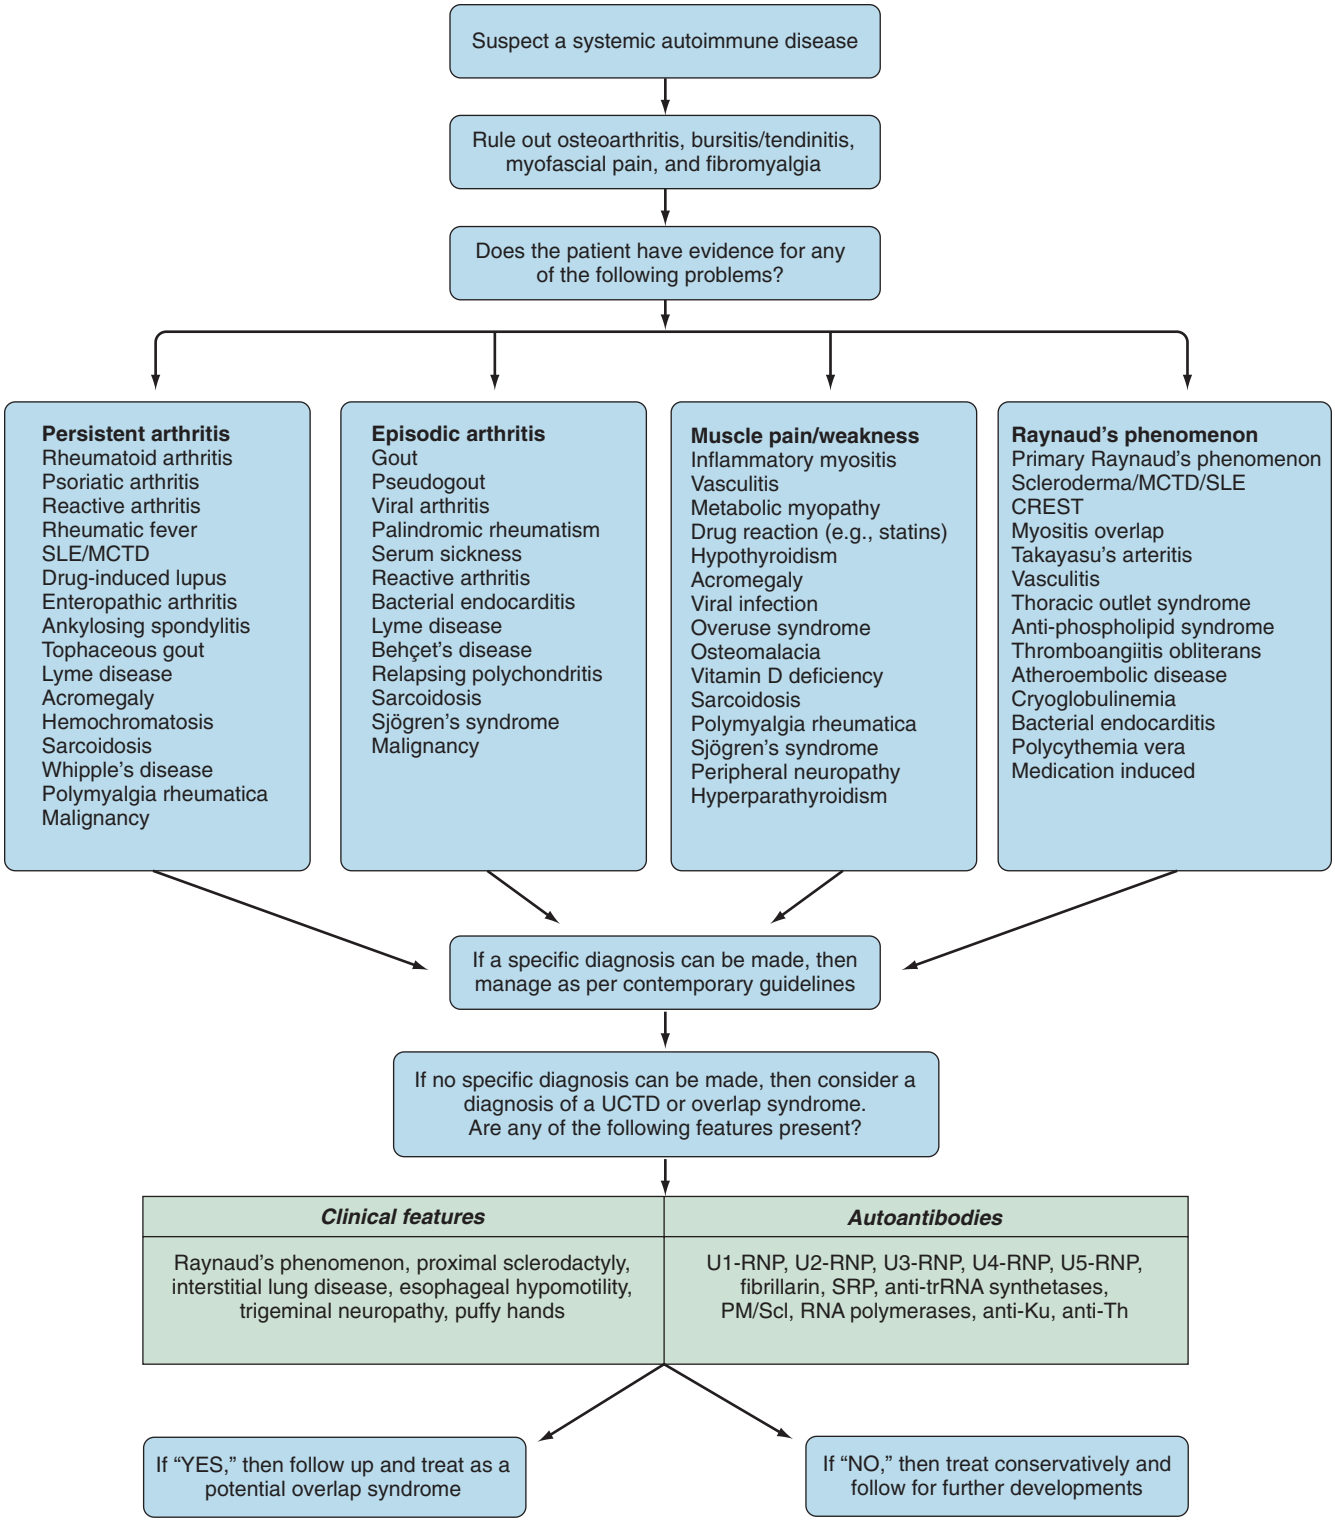

**Figure 86-4** Diagnostic algorithm for evaluating patients with undifferentiated connective tissue disease (UCTD). CREST, Calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly and telangiectasia; MCTD, mixed connective tissue disease; SLE, systemic lupus erythematosus.

disorders. In a 3-year follow-up of 51 patients with UCTDs, the ratios of Th17-cells to T cell regulatory subsets (either iTregs or Tregs) were evaluated with flow cytometry. Some 37.3% of the UCTD patients progressed to a systemic autoimmune disorder (SAID); the Th17/Treg ratio progressively increased from controls through UCTD patients, reaching the highest levels in patients in whom a defined systemic tissue disorder had developed (see Figure 86-4). This is a good example of how Tregs vary with disease expression and have the potential to be a prognostic marker.

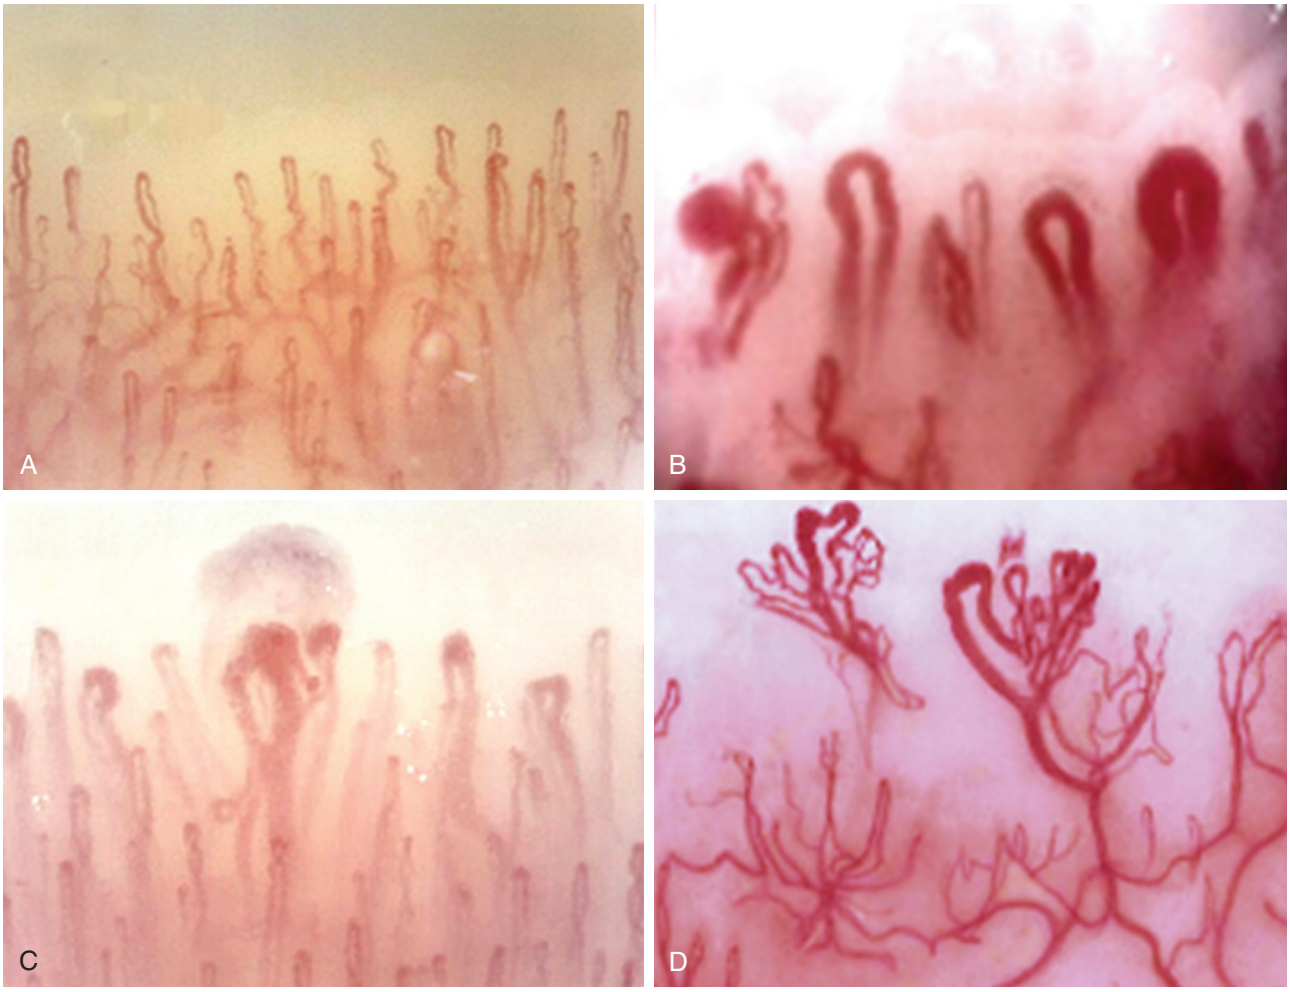

**Figure 86-5** Nailfold capillaroscopy in patients with systemic sclerosis and mixed connective tissue disease (MCTD). **A,** Normal capillaries. **B,** MCTD patient showing dilated and thickened capillary loops. **C,** Early scleroderma with irregular capillaries and mild dropout. **D,** Advanced scleroderma with capillary dropout and neoangiogenesis. *(Modified from Cutolo M. Capillaroscopy as an outcome measure for clinical trials on the peripheral vasculopathy in SSc—is it useful?* Int J Rheumatol *2010.)*

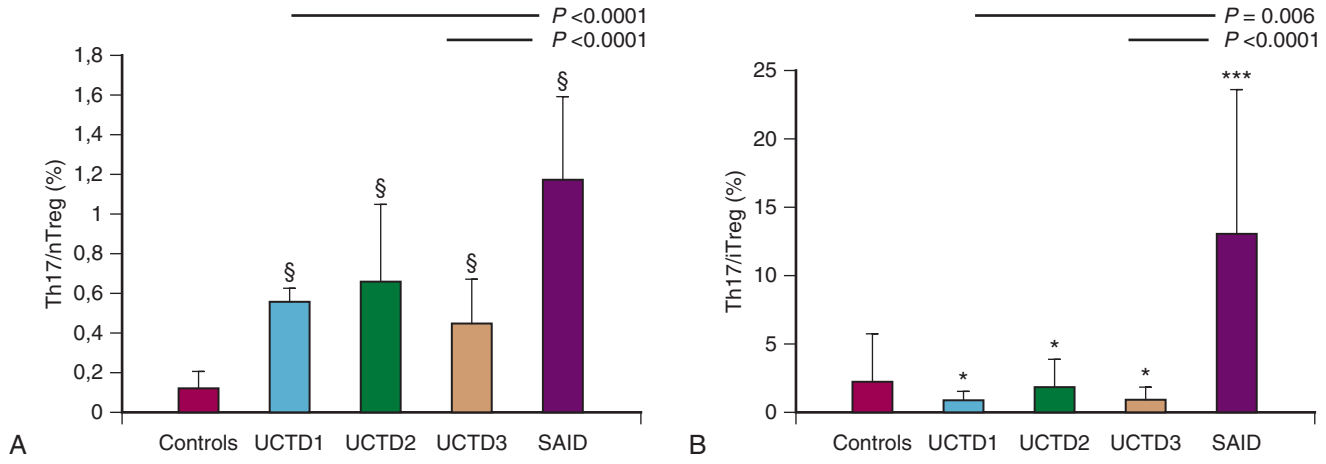

**Figure 86-6** The association of T helper (Th)17/natural Treg (nTreg) cells ratio in the evolution of undifferentiated connective tissue disease (UCTD) into differentiated systemic autoimmune disease (SAID). The ratio of Th cells producing interleukin 17 (Th17) to nTreg cells determines the propensity to develop an autoimmune disease as well as its intensity. Here it is seen that patients in various stages of UCTDs undifferentiated connective tissue diseases have a higher Th17/nTreg ratios than healthy controls but considerably lower than patients with SAID. **A,** Th17/nTreg (%) ratio in controls and patients with various stages of UCTDs and SAIDs. **B,** Th17/induced Treg (iTreg) (%) ratio in controls and patients with various stages of UCTD and SAIDs. UCTD1, UCTD2, UCTD3 (years of consecutive follow-ups). *(From Szodoray P, et al: Altered Th17 cells and Th17/regulatory T-cell ratios indicate the subsequent conversion from undifferentiated connective tissue disease to definitive systemic autoimmune disorders.* Hum Immunol *74:1510–1518, 2013.)*

## SCLERODERMA OVERLAP SYNDROMES

**KEY POINTS**

- **CREST has a common overlap with primary biliary cirrhosis.**
- **Scl overlap syndromes include Scl variants such as CREST, myositis associated with sclerodactyly and mixed connective tissue disease (MCTD)**
- **Raynaud's phenomenon is often the first clinical feature of SSc overlaps and has to be distinguished from primary cold Raynaud's (i.e., cold induced vasospasm).**
- **The finding of thickened and dilated capillaries on nailfold microscopy and pathological autoantibodies (e.g., Scl-70, anticentromere, PM/Scl, and U1-RNP) are important clues as to the development of an overlap syndrome.**
- **CREST has a common overlap with primary biliary cirrhosis.**
- **Pulmonary fibrosis and pulmonary hypertension are the main causes of morbidity/mortality.**
- **Scl like disorders (e.g., eosinophilic fasciitis, scleromyxedema, nephrogenic fibrosis, scleredema) need to be considered in the differential diagnosis of Scl overlaps.**

Scl has a widespread heterogeneity of disease expression, ranging from a diffuse cutaneous disease, with a poor prognosis, to a limited cutaneous involvement, with a mostly good prognosis. Scl often has overlaps with one or more connective tissue disorders which, in turn, have associations with specific autoantibodies. In many cases, these overlaps occur in patients who do not have prominent skin involvement (sine Scl) or with the limited form of the disease: CREST (calcinosis, Raynaud's phenomena, esophageal dysmotility, sclerodactyly, and telangiectasia). In a German registry of 3240 Scl patients, 10% had an overlap syndrome. They were predominantly female (82.5%), with a mean age of 48 years, and developed musculoskeletal involvement more frequently (62.5%) than patients with limited Scl (32.2%) or diffuse Scl (43.3%).

Some 90% of patients with Scl have a positive ANA, and specific antibody profiles are associated with distinctive patterns of morbidity and mortality in Scl.[38] Rheumatoid factor is found in approximately 60% of patients with Scl; 35% have clinically evident synovitis.[39] Anti-citrullinated protein antibody (ACPA)is a predictor of erosive arthritis.[40] Erosive arthritis also has an association with anti-RA33; the Scl component in such overlap patients is often an incomplete form of CREST.[41] Anticentromere antibodies (ACA) are most commonly seen in patients with CREST. Less often there are overlapping features with Sjögren's syndrome, RA and primary biliary cirrhosis.[42] Patients with ACA antibodies generally have a milder form of Scl, but there is an increased prevalence of isolated pulmonary hypertension and Hodgkin's lymphoma.[43,44]

Anti-PM/Scl antibodies are associated with a myositis/Scl overlap. These antibodies are associated with improved survival compared with dcSSc alone (91% vs. 65% at 10 years), despite having more muscle involvement and pulmonary fibrosis.[45] A European review of 114 Scl overlap patients reported a 95% PM-Scl[46] antibody positivity with 80% having an inflammatory myositis. Anti-PM/Scl antibodies are reactive with several proteins of the nucleolar PM/Scl macromolecular complex.[47] The two major components are the PM/Scl-75 and PM/Scl-100 epitopes. Antibodies to PM-1α (the major component of PM/Scl-100) are positively associated with a younger age of onset, inflammatory myopathy, calcinosis, inflammatory arthritis, and overlap features; they are negatively associated with interstitial lung disease and gastrointestinal involvement; and they produce a pattern of nucleolar staining on indirect immunofluorescence.[48] Muscle biopsies in PM/Scl overlap patients are distinguished by a high frequency of necrotic muscle fibers.

Anti-U3 RNP antibodies are also associated with skeletal muscle involvement and pulmonary hypertension.[49] Anti-U11/U12 antibodies are only seen in approximately 3% of Scl patients, but are strongly predictive of lung fibrosis.[50] Antimitochondrial antibodies (AMA) have an association with primary biliary cirrhosis and the limited form of Scl.[51] Interestingly, AMA are often reactive with the anti-70 and 50 kDa antibodies seen in patients with diffuse Scl,[52] thus providing an autoimmune link between the two disorders.

Antipolymerase III antibodies occurring in recent onset Scl have been associated with a diagnosis of cancer (mainly breast).[53]

The occurrence of anti-Ku in patients with Scl is often associated with inflammatory myopathy and interstitial lung disease.[54]

Several nonscleroderma fibrotic disorders may be mistaken for an Scl overlap at initial presentation (see Table 86-2). Although these disorders may have some systemic involvement, they seldom exhibit overlap features with other AICTDs.[55,56]

Scleromyxedema is characterized by cutaneous mucinosis and is often associated with a gammopathy, usually immunoglobulin (Ig)M and light chains.[60] The mucinous skin lesions appear as waxy papules on the face, neck, and limbs. If the papules coalesce, the condition may be mistaken for Scl (Figure 86-7A). Systemic involvement may occur with dysphagia, proximal muscle weakness, and pulmonary, cardiac, and renal complications. It is difficult

**Figure 86-7** Four examples of fibrosing disorders. **A,** Scleromyxedema (mucinous skin lesions appear as waxy papules on the face). **B,** Eosinophilic fasciitis (induration of skin and subcutaneous tissues). **C,** Scleredema (diffuse subcutaneous edema with swelling over right trapezius). **D,** Nephrogenic systemic fibrosis (coalescence of indurated nodules with joint contracture). *(Modified from Boin F, Hummers LK: Scleroderma-like fibrosing disorders.* Rheum Dis Clin N Am *34:1-17, 2008.)*

to manage; corticosteroids are usually tried initially, in refractory cases some benefit has been reported for intravenous immunoglobulin and thalidomide.

Eosinophilic fasciitis presents with limited Scl, such as skin changes involving the extremities (Figure 86-7B). The correct diagnosis is suggested by finding a peripheral eosinophilia and a hypergammaglobulinemia.[58] The definitive diagnosis is established by a full thickness skin biopsy that shows a diffuse inflammation of the fascia. MRI can confirm the thickened fascia and guide biopsy (Figure 86-8).[59] Initial treatment is with corticosteroids (prednisone, 0.5-1.0 mg/kg) tapering according to the clinical response; some patients need to continue moderate-dose corticosteroids for as long as 2 years.[58] Methotrexate and mycophenolate has been used in refractory cases.

Scleredema is a cutaneous mucinosis that often starts with a febrile episode and resolves spontaneously.[61] More chronic scleredema has been associated with paraproteinemias, including multiple myeloma and diabetes mellitus. The dermis is thickened with increased collagen glycosylation, as in diabetic stiff skin syndrome. The face and neck are commonly involved and there is relative sparing of the hands and feet (see Figure 86-7C). Systemic organ involvement is rare, but a monoclonal gammopathy is sometimes seen. Such cases need to be worked up for lymphoma. Refractory cases have been helped by local radiotherapy.

Nephrogenic systemic fibrosis (NSF) is a fibrotic disorder that, in some patients, develops following exposure to gadolinium-containing contrast agents. Most patients have pre-existing renal disease.[57] Histologically, there is fibroblast proliferation, thickened collagen bundles, and deposits of mucin, similar to those observed in scleromyxedema. The clinical presentation is a rapid progression with confluence of initially focal areas of indurated skin (see Figure 86-7D). The face is usually spared, but joint contractures may occur at the elbows and knees, and systemic involvement with pulmonary and neurological symptoms can develop in refractory cases. NSF is usually nonresponsive to corticosteroids and immunosuppressive therapy.

## LUPUS OVERLAP SYNDROMES

**KEY POINTS**

**Except for an overlap of SLE and rheumatoid arthritis, so-called "rhupus," and an overlap with Sjögren's syndrome, lupus overlaps are relatively uncommon.**

**SLE and RA overlap is seen in about 10% of SLE patients. The typical clinical picture is that of classical SLE in association with a deforming and often erosive arthritis; patients are often RF and ACPA positive.**

**An overlap of SLE and Sjögren's syndrome occurs in about 25% of lupus patients. These patients more commonly have Raynaud's phenomena than are classical SLE patients, and are usually positive for anti-Ro/SS-A antibodies.**

Unlike Scl overlaps, well-defined overlap syndromes with SLE are unusual. They mostly consist of isolated case reports of SLE associated with specific organ damage (e.g., hepatitis,

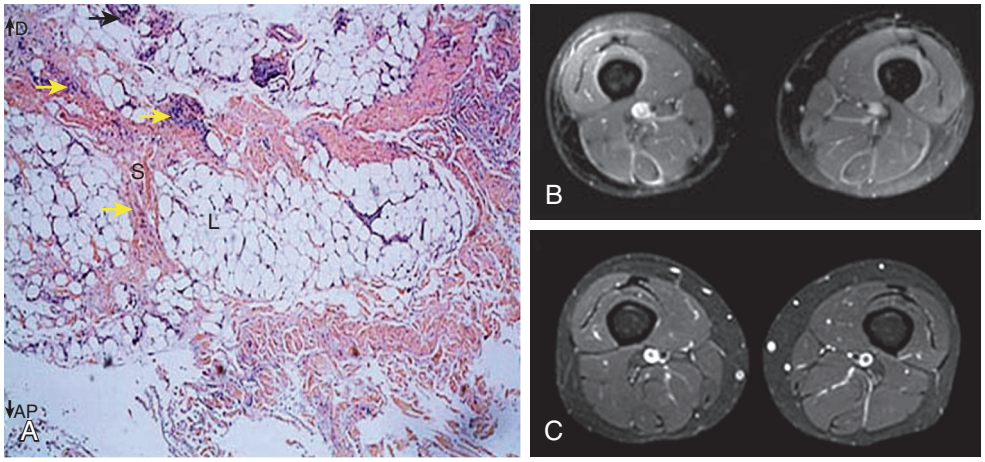

**Figure 86-8** The utility of magnetic resonance imaging in guiding the biopsy in a patient with eosinophilic fasciitis. **A,** Biopsy of quadriceps fascia (hematoxylin & eosin staining, magnification ×50). Deep dermis with fat lobules (L) and interlobular septas (S). Inflammatory cells composed of lymphocytes, mononuclear cells, and occasional eosinophilic cells, infiltrate the septa *(yellow arrows)*. **B,** Axial T2-weighted fat-suppressed MR images, showing thickening and signal hyperintensity of muscular fascias, involving both thighs. **C,** Axial T2-weighted fat-suppressed MR images (water IDEAL sequences) after corticosteroid treatment, showing normal findings, revealed complete remission. *(From Desvignes-Engelberet A, et al: From diagnosis to remission: place of MRI in eosinophilic fasciitis.* Clin Rheumatol *29:1461-1464, 2010; and modified from Pope JE: Other manifestations of mixed connective tissue disease.* Rheum Dis Clin N Am *31:519–533, 2005.)*

orchitis, and pancreatitis). The one exception is the overlap of RA and SLE, commonly referred to as "rhupus."[62] This overlap occurs in approximately 10% of SLE patients. The clinical picture is usually more consistent with SLE, with a deforming and often erosive arthropathy (Figure 86-9), accompanied by less severe renal involvement. Erosive arthritis in SLE is associated with the presence of ACPA.[63] This overlap must be distinguished from nonerosive Jaccoud's arthropathy, which is characterized by mild joint pain without synovitis, radiographs that show prominent ulnar deviation, swan neck deformities, and Z deformity of the thumb.

An overlap of SLE with Sjögren's syndrome (SS) occurs in some 10% to 25% of patients; typically in SLE patients aged 25 years or older.[64] The clinical picture is notable for a higher frequency of Raynaud's phenomena and a lower frequency of renal involvement, thrombocytopenia, and lymphadenopathy. The presence of anti-Ro/SS-A antibodies at the time of SLE diagnosis predicts the eventual development and SLE/SS overlap.[65]

## MYOSITIS OVERLAP SYNDROMES

| KEY POINTS |
|---|
| Myositis overlap syndromes are more common than the classic presentations of PM or DM. |
| Aminoacyl-tRNA synthetase (ARS) antibodies are associated with myositis, arthritis, and interstitial lung disease. |
| Arthritis and interstitial lung disease may antedate the appearance of myositis in patients with ARS. |
| Antibodies to synthetases, SRP, and nucleoporin tend to be associated with corticosteroid unresponsiveness. |
| Antibodies to U1RNP, PM-Scl, or Ku tend to be associated with corticosteroid responsiveness |
| Antibodies to TIF1-γ (p155/140) have been associated with an increased risk of myositis-associated malignancy. |

PM, DM and inclusion body myositis (IBM) and necrotizing autoimmune myositis (NAM) are the classic idiopathic inflammatory myopathies (IIM). Myositis-specific autoantibodies target proteins involved in key processes of protein synthesis and tend to be associated with distinctive clinical features within the spectrum of myositis.[66] These autoantibodies include the aminoacyl-tRNA synthetases (ARS), the Mi-2 helicase/histone deacetylase protein complex, and the signal recognition particle (SRP).[67] The ARS family of enzymes catalyze the transfer of a specific amino acid to its cognate transfer RNA. Antibodies against eight different ARS have been reported: Jo-1 (histidyl), PL-7 (threonyl), PL-12 (alanyl), OJ (isoleucyl), EJ (glycyl), KS (asparaginyl), Ha (tyrosyl) and Zo (phenylalanyl). The clinical features associated with ARS are often referred to as the "anti-synthetase syndrome:" a fluctuating inflammatory myopathy associated with fever, interstitial lung disease, Raynaud's syndrome, and mechanic's hands[68] (Figure 86-10). The arthritis of ARS may initially mimic RA with an inflammatory arthritis and nodules; erosions, however, do not occur.[69] Interstitial lung disease may be a presenting clinical feature of patients with ARS antibodies, with myopathy occurring much later. The association of myositis in patients with anti-U1-RNP antibodies is usually seen in the context of MCTD.[70] Antibodies to the SRP have been reported in 4% of patients with Scl/PM overlap; these patients usually have a severe, rapidly progressive myositis with prominent muscle fiber necrosis without much inflammatory cell infiltration.[71]

An association between DM and cancer has long been documented; this association has recently been linked to specific antibodies.[72] Breast, lung, and colorectal cancer are the most commonly associated cancers in Western countries, and nasopharyngeal carcinoma in China and Southeast Asia.[73] The patient's risk for cancer is highest during the first year after the diagnosis of the myositis, suggesting that the myopathy may occur as a paraneoplastic phenomenon. In this respect, the association of human transcriptional intermediary factor 1-gamma (TIF1-γ), formerly

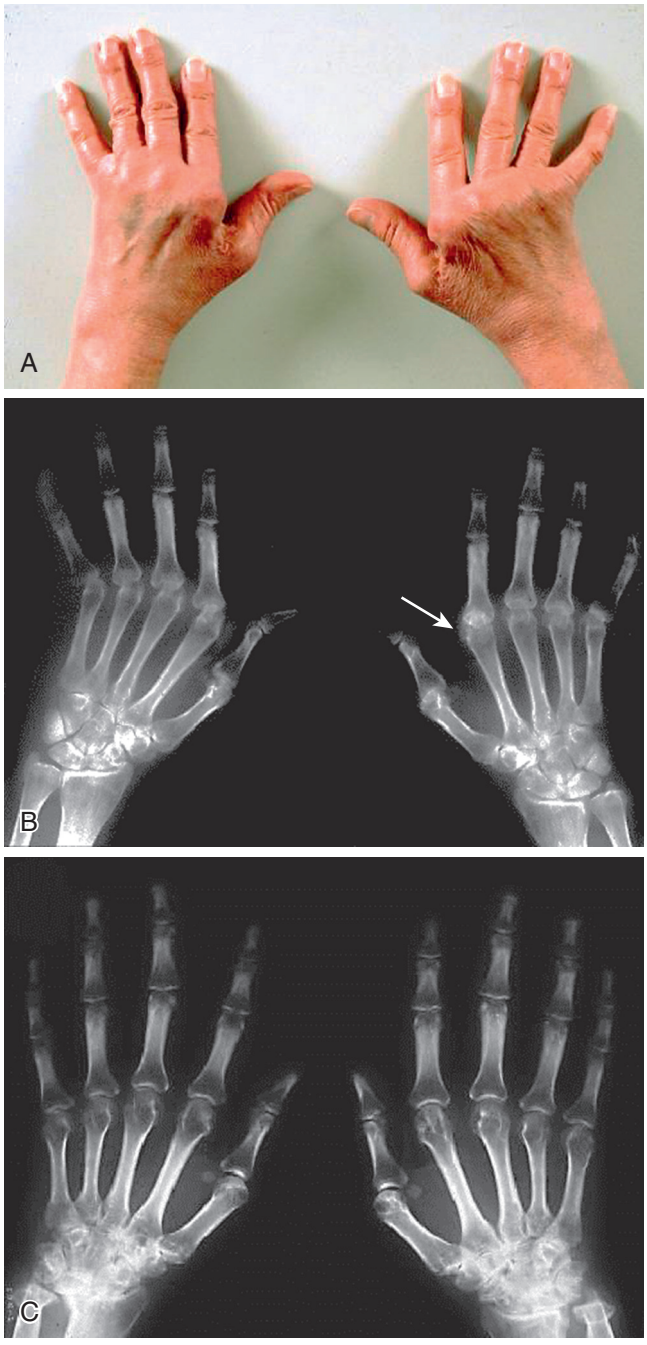

**Figure 86-9** Comparison of radiographic findings in a patient with rheumatoid arthritis (RA)/systemic lupus erythematosus (SLE) overlap (rhupus) and a lupus patient with Jaccoud's arthropathy. **A**, A 66-year-old woman was diagnosed with RA at 30 years and developed SLE at 37 years. The diagnosis of SLE was made based on the presence of leukopenia, positive anti-nuclear, anti-DNA, ribonuclear proteins, anti-Sm antibodies, and membranous-type lupus nephritis. Her rheumatoid factor was 1:320, and anticyclic citrullinated protein antibodies were 5.1 U/mL (normal <4.5). A recent radiograph of the patient's hands showed severe bilateral ulnar dislocation of the fingers without erosions in the metacarpophalangeal joints. The carpal bones were almost completely resorbed on the left side and fused on the right side. Diagnosis: rhupus. **B**, A 44-year-old female with a history of SLE starting at age 10 years, with malar rash, photosensitivity, leukopenia, oral ulcerations, alopecia, and a deforming arthropathy. The fingers' subluxations resemble rheumatoid arthritis but were completely reversible. Apart from some periarticular osteopenia, the radiographs are normal. In particular, there are no erosions. Diagnosis: Jaccoud's arthropathy *(From Nakamura J, et al: Radiographic features of rhupus arthropathy.* Intern Med *52:2837, 2013.)*

**Figure 86-10** Mechanic's hand in a patient with anti-synthetase syndrome. This patient with dermatomyositis presented with mechanics and (thickening and cracking of the skin, a result of hyperkeratosis), shortly followed by interstitial lung disease and arthritis. The presence of anti-Jo1 antibodies confirmed the suspicion of an anti-synthetase syndrome.

known as anti-p155/140, with idiopathic inflammatory myopathies is especially relevant.[74] TIF1-γ plays a key role in regulating the TGF-β signaling pathway, an essential intermediary in the development various types of cancer.

Overlap syndromes of inflammatory myopathy with SLE, Scl, MCTD, and Sjögren's syndrome are quite common.[75] Such overlaps, especially with Scl, have been reported as more common than the classic description of PM.[4] When clinical overlaps emerge, they are most commonly associated with specific autoantibodies: namely anti-PM-Scl, anti-Ku, U1 RNP, Jo-1, SRP.[76] A 2006 clinical and longitudinal study of 100 consecutive French-Canadian patients with idiopathic IIM concluded that the original Bohan and Peter classification of inflammatory myopathies should be abandoned, because 60% of patients with IIM were found to have overlap syndrome.[4] In this study, an overlap syndrome was based on the presence of an inflammatory myopathy as per the Bohan and Peter classification,[77] plus at least one clinical overlap feature (Table 86-3), or one of the following autoantibodies: synthetases, centromere, topo I, RNA-polymerases I or III, Th; U1RNP, U2RNP, U3RNP, U5RNP, Pm-Scl, Ku, SRP and nucleoporins (see Table 86-3). The distinction between classic PM/DM and an overlap syndrome was reported to be of prognostic/therapeutic significance, because classic PM nearly always manifested a chronic course, with 50% of patients initially unresponsive to corticosteroid therapy. Pure DM was almost always chronic, but most patients had an initial response to corticosteroids. On the other hand, patients with myositis overlap syndromes (usually with Scl features) were almost always responsive to corticosteroids (~90% response rate). When overlap patients were divided according to antibody subsets, anti-synthetase, SRP, and nucleoporin aAbs were markers for treatment-resistant myositis, whereas aAbs to U1RNP, PM-Scl, or Ku were markers for corticosteroid responsiveness. Patients with autoimmune myositis, especially DM are at risk for cancer,[78] and it has been problematic as to how far and how often one should pursue a

**TABLE 86-3** Suggested Classification for Inflammatory Myopathies

| Abbreviation | Description |
|---|---|
| PM | Pure polymyositis |
| DM | Pure dermatomyositis |
| OM | Overlap myositis: myositis with at least 1 clinical overlap feature and/or an overlap autoantibody |
| CAM | Cancer-associated myositis: with clinical paraneoplastic features and without an overlap autoantibody or anti-Mi-2 |
| **Definition of Polymyositis** | |
| 1) Symmetric proximal muscle weakness | |
| 2) Elevation of serum skeletal muscle enzymes | |
| 3) Electromyographic triad of short, small, polyphasic motor unit potentials; fibrillations, positive sharp waves and insertional irritability; and bizarre, high-frequency repetitive discharges | |
| 4) Muscle biopsy abnormalities of degeneration, regeneration, necrosis, phagocytosis, and an interstitial mononuclear infiltrate | |
| 5) Typical skin rash of DM, including the heliotrope rash, Gottron sign, and Gottron papules | |
| • *Definite myositis:* 4 criteria (without the rash) for PM, 3 or 4 criteria (plus the rash) for DM | |
| • *Probable myositis:* 3 criteria (without the rash) for PM, 2 criteria (plus the rash) for DM | |
| • *Possible myositis:* 2 criteria (without the rash) for PM, 1 criterion (plus the rash) for DM | |
| **Definition of Clinical Overlap Features** | |
| Inflammatory myopathy plus of the following clinical findings: polyarthritis, Raynaud's phenomenon, sclerodactyly, scleroderma proximal to the metacarpophalangeal joints, typical systemic sclerosis-type calcinosis in the fingers, lower esophageal or small-bowel hypomotility, diffusing capacity for carbon monoxide lower than 70% of the normal predicted value, interstitial lung disease on chest radiogram or computed tomography scan, discoid lupus, anti-native DNA antibodies plus hypocomplementemia, four or more of 11 American College of Rheumatology systemic lupus erythematosus criteria, anti-phospholipid syndrome | |
| **Definition of Overlap Autoantibodies** | |
| Anti-synthetases (Jo-1, PL-7, PL-12, OJ, EJ, KS), scleroderma (Scl)-associated autoantibodies (Scl-specific antibodies: centromeres, topo I, ribonucleic acid-polymerases I or III, Th; and antibodies associated with Scl in overlap: U1RNP, U2RNP, U3RNP, U5RNP, Pm-Scl, Ku), and other autoantibodies (SRP, nucleoporins) | |
| **Definition of Clinical Paraneoplastic Features** | |
| Cancer within 3 yrs. of myositis diagnosis, plus the absence of multiple clinical overlap features, plus if cancer was cured, myositis was cured as well | |

Modified from Troyanov Y, et al: Novel classification of idiopathic inflammatory myopathies based on overlap syndrome features and autoantibodies: analysis of 100 French Canadian patients. *Medicine (Baltimore)* 84(4):231-249, 2005.

malignancy work-up. It is now apparent that the finding of an antibody against 155 kDa and 140 kDa protein specificities (anti-155/140 antibody) signifies a significant risk for the co-occurrence of a malignancy and points to the need for a thorough cancer work-up.[79]

## MIXED CONNECTIVE TISSUE DISEASE

**KEY POINTS**

- **The clinical overlap features of MCTD (i.e., Scl, SLE and PM/DM) seldom occur concurrently, but develop sequentially over months or years.**
- **Raynaud's phenomenon is seen in nearly all patients with MCTD; if it is absent, the diagnosis should be reconsidered.**
- **About 25% of MCTD patients develop renal involvement—usually membranous glomerulonephritis. Proliferative glomerulonephritis is uncommon in MCTD.**
- **Serious CNS involvement is rare in MCTD; the most common neurologic findings are trigeminal neuropathy and sensorineural hearing loss.**
- **Pulmonary HTN is the most common cause of death in MCTD patients, and it should be screened for on an ongoing basis.**

MCTD was described by Sharp and colleagues in a 1972 paper reporting an overlap of SLE, Scl, and PM.[80] This was the first overlap syndrome defined in terms of a specific antibody, namely, antibodies to a ribonuclease-sensitive extractable nuclear antigen (ENA). During the last 38 years, many studies have explored the clinical correlates of this antibody system (now called *U1 RNP*).

### Serologic Features

The basic premise of the MCTD concept is that the presence of high-titer anti-U1 RNP antibodies modifies the expression of a DCTD in ways which are relevant to prognosis and treatment.[81] The first clue to diagnosing MCTD is usually a positive ANA with a high titer speckled pattern. The titer is often greater than 1:1000 and sometimes greater than 1:10,000. This finding should prompt the measurement of antibodies to U1-RNP, Sm, Ro, and La. It is also pertinent to note whether the serum contains antibodies to dsDNA and histones, because patients destined to follow a course most consistent with MCTD have sera with predominant U1-RNP reactivity. Antibodies to dsDNA, Sm, and Ro are occasionally seen as a transient phenomenon in patients with MCTD. But when they are found

consistently, as the predominant antibody system, the clinical picture is usually more consistent with classic SLE. Antibodies to the 70 kDa antigen, especially in its apoptotic form, are most closely associated with the clinical correlates of MCTD.[10]

## Clinical Features

### Diagnosis

MCTD is an overlap syndrome that embraces features of SLE, Scl, and PM/DM.[82] These overlap features seldom occur concurrently. It usually takes several years before enough overlapping features have appeared for one to be confident that MCTD is the most appropriate diagnosis.[83] The most common clinical associations with U1 RNP antibodies in the early phase of the disease are hand edema, arthralgia, Raynaud's phenomenon, inflammatory muscle disease, and sclerodactyly. No American College of Rheumatology criteria exist for diagnosis of MCTD, but a comparative study reported that two criteria sets, those of Alarcon-Segovia and Kahn, had the best sensitivity and specificity (62.5 % and 86.2%, respectively)[84] (Table 86-4). The sensitivity could be improved to 81.3% if the term "myalgia" was substituted for "myositis."[85] Some patients initially diagnosed with MCTD will evolve into a clinical picture most consistent with SLE or RA. In one long-term follow up more than half of the patients continued to satisfy criteria for MCTD.[86] A comparison of the clinical and serologic features of MCTD with SLE, RA, Scl, and PM/DM is given in Table 86-4.

### Early Symptoms

In the early stages, most patients destined to develop MCTD cannot be differentiated from patients with other classic AICTDs (Table 86-5). The assumption that a diagnosis of MCTD implies a simultaneous presence of features usually seen in SLE, Scl, and PM is erroneous. It is unusual to see such an overlap during the early course of MCTD, but with the progress of time the overlapping features usually occur sequentially. Early in the course of the disease, most patients complain of fatigue, poorly defined myalgias, arthralgias, and Raynaud's phenomenon. At this point in time a diagnosis of RA, SLE, or UCTD seems most appropriate.[1] If such a patient is found to have swollen hands and/or puffy fingers in association with a high-titer speckled ANA, they should be carefully followed up for the evolution of overlap features (see Table 86-3). A high titer of anti-RNP antibodies in a patient with UCTD is a powerful predictor for a later evolution into MCTD. Less commonly, there is an acute onset of MCTD, which gives little clue to the subsequent course; such presentations have included PM, acute arthritis, aseptic meningitis, digital gangrene, high fever, acute condition in the abdomen, and trigeminal neuropathy.[87]

**TABLE 86-4** Two Diagnostic Criteria for Mixed Connective Tissue Disease

| Alarcón-Segovia Criteria | Kahn Criteria |
|---|---|
| **A. Serologic Criteria**<br>Anti-RNP at hemagglutination titer of ≥1:1600 | **A. Serologic Criteria**<br>High-titer anti-RNP corresponding to a speckled ANA of ≥1:1200 titer |

| **MCTD Present if:**<br>Criterion A is accompanied by three or more clinical criteria—one of which must include synovitis or myositis. | **MCTD Present if:**<br>Criterion A is accompanied by Raynaud's phenomenon and two or more of the three remaining clinical criteria. |

ANA, Anti-nuclear antibodies; MCTD, mixed connective tissue disease; RNP, ribonuclear protein.

From Bischoff L, Derk CT: Eosinophilic fasciitis: demographics, disease pattern and response to treatment: report of 12 cases and review of the literature. *Int J Dermatol* 47(1):29-35, 2008.

### Fever

Fever may be a prominent feature of MCTD in the absence of an obvious cause.[87] Fever of unknown origin has been the initial presenting symptom of MCTD; after careful evaluation, fever in patients with MCTD can usually be traced to a coexistent myositis, aseptic meningitis, serositis, lymph adenopathy, or intercurrent infection.[87]

### Bones and Joints

Joint pain and stiffness is an early symptom in nearly all patients in whom the MCTD syndrome develops. During the past 2 decades it has become increasingly apparent that joint involvement in MCTD is more common and more severe than in classic SLE.[88] An obvious arthritis, often with deformities commonly seen in RA (e.g., ulnar deviation and swan neck and boutonniere deformities),[89] eventually develops in approximately 60% of patients with MCTD (Figure 86-11). Radiographs usually show a characteristic absence of severe erosive changes, and they often resemble Jaccoud's arthropathy. Small marginal erosions, often with a well-demarcated edge, are the most

**Figure 86-11** Deforming arthritis in a patient with mixed connective tissue disease, characterized by MCP synovitis, ulnar deviation, and swan neck deformities. These findings are clinically indistinguishable from rheumatoid arthritis, including the presence of erosions. *(Courtesy Robert M. Bennett, MD.)*

MCTD, Mixed connective tissue disease; PM, polynyositis; RA, rheumatoid arthritis; SCL, scleroderma; SLE, systemic lupus erythematosus.

**Figure 86-12** A radiograph of a patient with mixed connective tissue disease, showing two small, well-demarcated erosions *(arrows)* at the base of the second and third phalanxes. *(Courtesy Robert M. Bennett, MD.)*

characteristic radiologic feature in patients with severe joint disease[90] (Figure 86-12). However, a destructive arthritis, including an arthritis mutilans, is a well-established association[89] (Figure 86-13). Erosive disease typically starts approximately 5 years after the onset of MCTD and is usually associated with ACPA positivity.[40,91]

Flexor tenosynovitis, bone edema, and pericapsular inflammation reminiscent of a seronegative spondyloarthropathy develops in some patients. In a follow-up study of 201 MCTD patients, Szodoray found osteoporosis in 32.3%, whereas 18.9% had osteoporotic vertebral fractures (mainly those on long-term corticosteroids).[91]

## Skin and Mucous Membranes

Mucocutaneous changes develop in most patients with MCTD sometime during the course of the syndrome.[92] Raynaud's phenomenon is the commonest problem, and one of the earliest manifestations of MCTD.[93] It may be accompanied by puffy, swollen digits and, sometimes, total hand edema.[87] In some patients, skin changes commonly associated with classic SLE are prominent findings, particularly malar rash and discoid plaques (Figure 86-14). Other problems include buccal ulceration, sicca complex, orogenital ulceration, livedo vasculitis, subcutaneous nodules, and nasal septal perforation.

## Muscle

Myalgia is a common symptom in patients with MCTD syndrome. In most patients there is no demonstrable weakness, EMG abnormalities, or muscle enzyme changes. It is

**Figure 86-13** A radiograph of a patient with mixed connective tissue disease with a destructive arthritis and digital osteolysis. *(Courtesy Robert M. Bennett, MD.)*

often unclear whether the symptom represents a low-grade myositis, physical deconditioning, or an associated fibromyalgia syndrome. The inflammatory myopathy associated with MCTD is similar histologically to IIM, with features of both the vascular involvement as DM and cell-mediated changes of PM.[94] In most patients, myositis occurs as an acute flare against a background of general disease activity. Such patients usually respond well to a short course of high-dose corticosteroid therapy. Another scenario is that of a low-grade inflammatory myopathy, which is often insidious

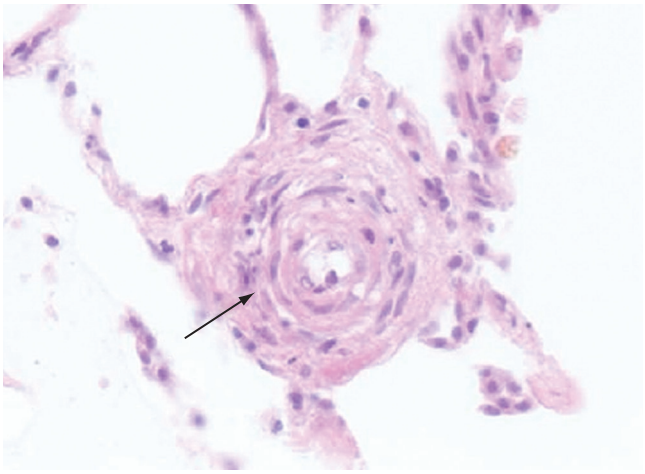

**Figure 86-15** Intimal hyperplasia and smooth muscle hypertrophy without accompanying inflammation are the characteristic features of the vasculopathy of mixed connective tissue disease. When it occurs in the lung, as shown here, it may give rise to severe pulmonary hypertension. (Note absence of pulmonary fibrosis.) The plexiform lesion *(arrow)* is a characteristic pathologic finding in this disease process. *(From Bull TM, et al: Pulmonary vascular manifestations of mixed connective tissue disease.* Rheum Dis Clin N Am *31:451–464, 2005.)*

in its onset. These patients often have a poor therapeutic response to corticosteroids. An impressive fever develops in some patients with PM associated with MCTD[87]; other patients may give a history of febrile myalgias that have been diagnosed as "flu."

## Blood Vessels

Raynaud's phenomenon is an early feature of nearly all patients who are eventually diagnosed with MCTD.[93] A bland intimal proliferation and medial hypertrophy that affects medium- and small-size vessels is the characteristic vascular lesion of MCTD[95] (Figure 86-15) and is also the characteristic pathology in pulmonary hypertension and renovascular crises. Both nailfold capillary microscopy[96] and color Doppler[97] are useful in distinguishing benign primary Raynaud's phenomenon from secondary involvement in MCTD and other AICTDs (see Figure 5). Fingernail capillaroscopy in MCTD patients shows the same pattern of capillary dilation and drop out that has been reported in Scl.[98,99] An angiographic study reported a high prevalence of medium-size vessel occlusions[100] (Figure 86-16). As in SLE, premature atherosclerosis is a problem in many MCTD patients.[101] Risk factors include dyslipidemia, anticardiolipin antibodies, endothelial cell antibodies, and persistent chronic inflammation.[102] Antibodies to heat shock protein (HSP)60 have a strong association with atherosclerotic disease in MCTD and provide a direct indication of endothelial cell injury.[103]

## Heart

All three layers of the heart may be involved in MCTD.[104] An abnormal electrocardiogram (EKG) is seen in approximately 20% of patients. The most common EKG changes are right ventricular hypertrophy, right atrial enlargement, and interventricular conduction defects. Pericarditis is the

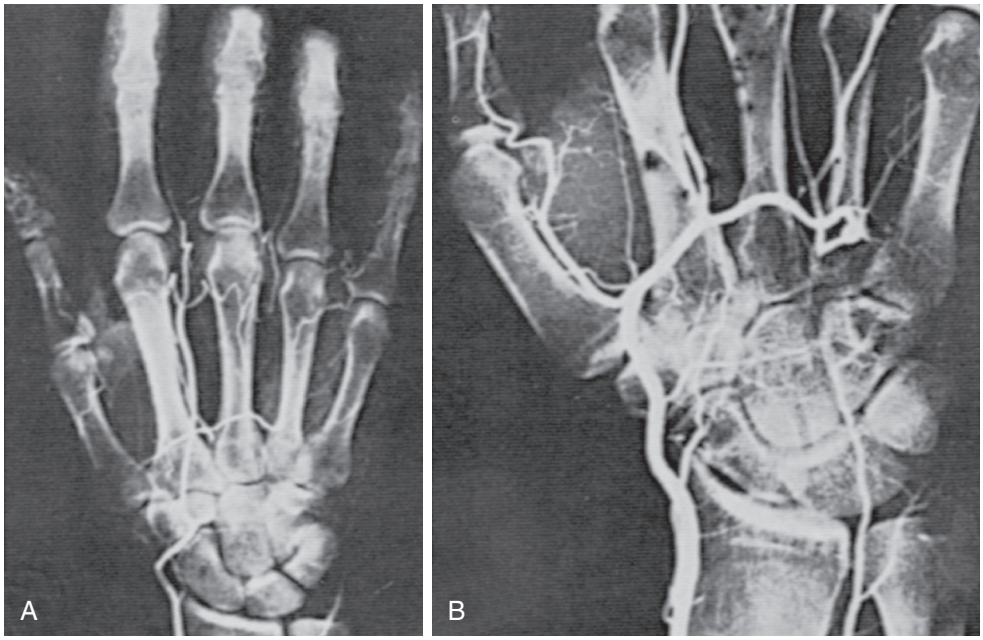

**Figure 86-16** **A**, Digital angiogram showing multiple arterial occlusions with collateral formation. **B,** Digital angiogram showing ulnar artery occlusions. *(From Peller JS, et al: Angiographic findings in mixed connective tissue disease: correlation with fingernail capillary photo-microscopy and digital photoplethysmography findings.* Arthritis Rheum *28:768, 1985. Reprinted with permission of the American College of Rheumatology.)*

most common clinical manifestation of cardiac involvement, reported in 10% to 30% of patients, whereas pericardial tamponade is rare. Involvement of the myocardium is increasingly recognized. In some patients, myocardial involvement is secondary to pulmonary hypertension (PAH); this occurs in approximately 20% of patients and is often asymptomatic in its early stages.[105] The early detection of pulmonary hypertension is increasingly important, because there are now more effective therapeutic options. PAH is probably underdiagnosed in its early stages. In a community rheumatology practice setting, an elevation of the estimated right ventricular systolic pressure (ERVSP), consistent with the diagnosis of PAH, was found in 13% of previously undiagnosed patients.[106] This diagnosis should be suspected in patients with increasing exertional dyspnea. Two-dimensional echocardiography with Doppler flow studies is the most useful screening test. A definitive diagnosis requires cardiac catheterization showing a mean resting pulmonary artery pressure greater than 25 mm Hg at rest. The development of pulmonary hypertension has been correlated with a nailfold capillary pattern similar to that seen in Scl, anti-endothelial cell antibodies, anti-cardiolipin antibodies, and anti-U1-RNP antibodies.[107] Regular electrocardiograms and echocardiographic evaluations are recommended for all MCTD patients, because subclinical disease is found in as many as 38% of patients.[104]

## Lung

Lung involvement occurs in as many as 75% of patients.[108] Early symptoms that should prompt further investigation are dry cough, dyspnea, and pleuritic chest pain.[109] PAH is prognostically the most severe form of pulmonary involvement in MCTD (Figure 86-17). In a Norwegian cohort of unselected MCTD patients, the overall prevalence of PAH was 3.4%; all those afflicted had elevated levels of N-terminal probrain natriuretic peptide (NT-proBNP).[110] Unlike Scl, in which pulmonary hypertension is often secondary to an interstitial pulmonary fibrosis, PAH in MCTD is usually caused by a bland intimal proliferation and medial hypertrophy of pulmonary arterioles[111] (see Figure 86-15). Interstitial lung disease (ILD), occurs in as many as 50% of patients. High-resolution computed tomography (HRCT) is the most sensitive test to determine the presence of ILD.[112] The most common HRCT findings are septal thickening and ground-glass opacities. Untreated ILD is usually progressive, with the development of severe pulmonary fibrosis in 25% of patients after 4 years of follow-up.[113]

## Kidney

In the initial description of MCTD, renal involvement was considered rare.[114] After 4 decades of observation, it is now evident that renal involvement occurs in approximately 25% of patients.[115] However, high titers of anti-U1 RNP antibodies are relatively protective against the development of diffuse proliferative glomerulonephritis, regardless of whether they occur in a setting of classic SLE or MCTD. When renal changes do develop in patients with MCTD, they usually take the form of a membranous glomerulonephritis.[116] This is often asymptomatic but may sometimes cause an overt nephrotic syndrome.[115] The development of diffuse proliferative glomerulonephritis or parenchymal interstitial disease has been rarely recorded in MCTD. There is increasing recognition that MCTD patients are at risk of developing a renovascular hypertensive crisis similar to the Scl kidney.

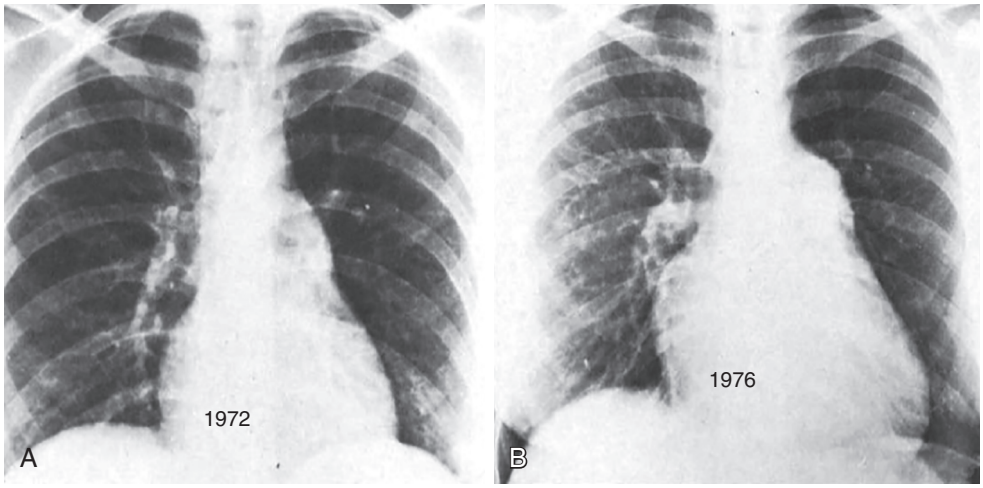

**Figure 86-17** A patient with mixed connective tissue disease with progressive pulmonary hypertension. In 1972, there was mild dilatation of the pulmonary trunk, but the heart and lungs were otherwise normal. By 1976, there was cardiac dilatation with increased enlargement of the pulmonary trunk and proximal pulmonary arteries. This picture is the typical appearance of severe pulmonary arterial hypertension. *(Courtesy Robert M. Bennett, MD.)*

### Gastrointestinal

Gastrointestinal involvement is a major feature of the overlap with Scl, occurring in approximately 60% to 80% of patients.[88] The most common abdominal problem in MCTD is disordered motility in the upper gastrointestinal tract. Histologically, this manifests as severe atrophy and loss of smooth muscle cells in the muscular layer of the lower esophagus, followed by fibrosis. Immunostaining is positive for anti-IgG and anti-C3 antibodies, but not for anti-IgM antibodies.[117] IgG immunoglobulins separated from the sera of MCTD patients were reactive with esophageal smooth muscle cells from non-CTD patients, suggesting an immune-mediated trigger for esophageal disease. There have been case reports of hemoperitoneum, hematobilia, duodenal bleeding, megacolon, pancreatitis, ascites, proteins loosing enteropathy, primary biliary cirrhosis, portal hypertension, pneumatosis intestinalis, and autoimmune hepatitis.[118] Abdominal pain in MCTD may result from bowel hypomotility, serositis, mesenteric vasculitis, colonic perforation, and pancreatitis. Malabsorption syndrome can occur secondarily to small bowel dilation with bacterial overgrowth. Liver involvement in the form of chronic active hepatitis and Budd-Chiari syndrome has been described. Pseudodiverticulae, identical to those seen in SCC, may be seen along the antimesenteric border of the colon.

### Nervous System

In keeping with Sharp's original description, CNS involvement has not been a conspicuous feature of MCTD. The most common problem is a trigeminal neuropathy.[119,120] In a review of 81 case of trigeminal neuropathy seen in a neurologic clinic, the most frequently associated CTDs were UCTD (47%), mixed connective tissue disease (26%), and Scl (19%). A sensorineural hearing loss has been reported in nearly 50% of MCTD patients.[121] In contrast to CNS involvement in classical SLE, frank psychosis and convulsions have rarely been reported in MCTD.[119] In a similar vein, cognitive function in MCTD is relatively unimpaired compared with SLE.[122] Headaches are a relatively common symptom; in the majority of patients they are vascular in origin with many of the components of classic migraine. In a subset of these patients, signs of meningeal irritation develop and examination of the cerebral spinal fluid reveals the changes of aseptic meningitis.[123] Aseptic meningitis in MCTD has also been described as a hypersensitivity reaction to nonsteroidal antiinflammatory drugs (NSAIDs), in particular sulindac and ibuprofen. There are isolated reports of transverse myelitis, cauda equina syndrome, cerebral hemorrhage, retinal vasculitis, optic neuropathy, progressive multi-focal leukoencephalopathy, cold-induced brain ischemia, myasthenia gravis, polyradiculopathy, demyelinating disorder, and peripheral neuropathy. Elevated CSF levels of anti-U1 RNP antibodies, with a predominance of anti-70 kDa antibodies, have been reported in both SLE and MCTD patients with diffuse central neuropsychiatric involvement.[124] Many patients with AICTDs have changes on brain MRI that are referred to as *unspecific bright objects* (UBO). In many instances UBOs occur in the absence of neurologic symptoms. However, there is a modest correlation between the density and positioning of UBOs; in MCTD these lesions tend to cluster at the corticomedullary junction and periventricular region.[125]

### Blood

Hematologic abnormalities are a common finding in MCTD. Anemia is found in 75% of patients, the usual profile is most consistent with the anemia of chronic inflammation.[88] A positive Coombs test is seen in approximately 60% of patients, but an overt hemolytic anemia is uncommon.[126] As in SLE a leukopenia affecting mainly the lymphocyte series is seen in approximately 75% of patients and tends to correlate with disease activity. Less common associations are thrombocytopenia, thrombotic thrombocytopenia purpura, and red cell aplasia. Hypocomplementemia has been

described in several studies[88]; it is not as prevalent as in classic SLE and has not been correlated with any particular clinical situation. Positive tests for rheumatoid factor (RF) have been found in approximately 50% of patients.[127] The presence of RF is associated with more severe degrees of arthritis, especially if anti-A2/RA33 are also present.[14] ACPAs occur in some 60% of MCTD patients and are strongly correlated with the presence of erosive disease.[63,91] Anti-cardiolipin antibodies and/or lupus anti-coagulants are a common occurrence and have been associated with vasculopathy and increased mortality.[128] Unlike the anti-cardiolipin antibodies found in SLE they are β2-glycoprotein independent and tend to be associated with thrombocytopenia rather than thrombotic events.[129]

### Pregnancy

Reports of maternal and fetal morbidity in MCTD are quite diverse.[130] In a comparison study of patients with MCTD and SLE, the fertility rates in patients with diseases were unaltered, whereas the parity and fetal wastage was increased in both.[131] Some studies have reported an exacerbation of MCTD during pregnancy and postpartum flares,[131] whereas others have not. Anti-endothelial antibodies have been linked to spontaneous abortion in MCTD.[132] A single case of neonatal "lupus" has been reported, suggesting a pathogenic role for the transplacental passage of anti-U1 RNP antibodies.[133]

### Juvenile Mixed Connective Tissue Disease

MCTD may first become apparent in childhood. The average age of onset in one report was 10.7 years.[134] Polyarthritis and Raynaud's phenomena are the most common presenting features. There tends to be a progression of organ involvement with 20% involvement at 5 years and 48% at ten years. Significant myocarditis, glomerulonephritis, thrombocytopenia, seizures, hemolytic uremic syndrome, an acute coronary syndrome, and aseptic meningitis have been described in isolated cases.

### Is Mixed Connective Tissue Disease a Distinct Clinical Entity?

Despite the 40 years that have passed since the initial description of MCTD, there remains some hesitation in designating it a "real disease." Ten years after the initial description, some researchers were asking "does MCTD exist?"[134a] or "MCTD—a decade of growing pains."[134b] After a further 10 years more strident titles appeared, including "MCTD—goodbye to all that"[134c] and "MCTD: fact or fiction"[134d] and "MCTD—33 years of uncertainty."[134e] One of the major areas of uncertainty was whether MCTD described an intermediate phenotype, which would eventually evolve into one of the better established CTDs, such as Scl or SLE. In 2012 Capelli et al. reported on 161 MCTD patients that had been followed up for a mean of 8 years. They found that the MCTD label was still appropriate in 75% of the initial cohort, with the conditions of 17% evolving into SCL, 9.1% into SLE, then 2.5%, in turn, into RA. They concluded that "MCTD is a distinct clinical entity, but a subgroup of patients may evolve into another CTD." By 2014 the concept of MCTD as a relevant entity was better established. A pathogenetic role for anti-U RNP antibodies was emerging, especially with regard to clinical features of Raynaud's phenomena and esophageal dysmotility and prognosis in regards to PAH.[135] Diseases as "diagnostic entities" are difficult to reliably authenticate. It is evident that the autoimmune connective tissue disorders cannot be designated as "diseases" on the basis of Koch's postulates." The overlaps of SLE and Scl described in this chapter attest to this conundrum. However, it is now evident that patients with persistently high levels of anti-U1RNP antibodies often manifest a clinical picture of Raynaud's phenomena, esophageal dysmotility, polyarthritis (sometimes erosive), puffy hands/fingers, and absence of severe renal or neuropsychiatric disease. On the other hand, interstitial lung disease and PAH (which is often fatal) are more likely to develop in these patients. When all is said and done, it is important to remain grounded and not let one's clinical judgment be swayed by esoteric pronouncements on whether your patient has a disease, an entity, or a syndrome.

## MANAGEMENT OF OVERLAP SYNDROMES

**KEY POINTS**

**The management of overlap syndromes has not been the subject of controlled trials.**

**Management is therefore based on an analysis of the clinical features and the application of management strategies used in the usual treatment presenting features in terms of inflammatory arthritis, Raynaud's phenomenon, inflammatory muscle disease, serositis, interstitial lung disease, pulmonary hypertension, and the gastrointestinal features of Scl.**

**By definition, the clinical features of an overlap syndrome will be diverse and can change over time. Thus a reappraisal of management strategies is needed at each patient encounter.**

The rational management of overlap CTDs is confounded by the absence of controlled trials. Recommendations for management are based on conventional treatments for SLE, PM/DM, RA, and Scl.[136] General guidelines to treat specific features of the overlap CTDs are given in Table 86-6. Almost all patients with CTDs experience Raynaud's phenomenon. Apart from advice on minimizing cold exposure, most patients should be given calcium blockers (e.g., nifedipine). The use of topical nitrates, endothelin antagonists (e.g., bosentan), phosphodiesterase-5 inhibitors (e.g., tadalafil), prostaglandin analogs (e.g., iloprost) should be considered in severe refractory cases.[137] Pulmonary hypertension is the main cause of death in MCTD, and patients should be evaluated at regular intervals for this complication; early intervention is the key to effective management. Recent advances in the treatment of pulmonary hypertension have led to reduced morbidity and mortality.[111] Overall, effective management requires anticoagulation and vasodilator therapy, such as calcium channel blockers or prostacyclin analogues. Long-term treatment with intravenous epoprostenol or prostacyclin improves exercise capacity, hemodynamics, and survival in many patients[138] as does therapy with inhaled iloprost.[139] There is evidence that

**TABLE 86-6** Guidelines for Managing Overlap Syndromes

| System Involved | *Problems* | Treatments |
|---|---|---|
| Non-specific | *Fatigue, arthralgias, myalgias* | NSAIDs, anti-malarials, low-dose prednisone (<10 mg/day)<br>Trial use of modafinil |
| | *Vascular headache* | Trial of propranolol and/or alternate-day aspirin, 350 mg<br>Symptomatic use of a triptan (e.g., sumatriptin, eletriptan) |
| Blood | *Autoimmune anemia and thrombocytopenia* | High dose steroids (prednisone, ~80 mg/day) with taper dependent on clinical course. Consider danazol, IVIG and immunosuppression in recalcitrant cases |
| | *Thrombotic thrombocytopenic purpura* | Immediate infusion of fresh frozen plasma. May require plasma exchange and transfusion of platelet depleted RBCs. Consider splenectomy in recalcitrant cases |
| Vascular | *Raynaud's phenomenon* | Keep warm, avoid finger trauma, avoid β-blockers, stop smoking. Dihydropyridine Ca channel blockers (e.g., nifedipine). Alpha sympatholytics (e.g., prazosin). Consider endothelin receptor antagonist (e.g., bosentan) in recalcitrant cases |
| | *Acute-onset digital gangrene* | Local chemical sympathectomy (infiltration of lidocaine at base of involved digit). Anti-coagulation. Topical nitrates. Consider hospitalization for intra-arterial prostacyclin. Start endothelin receptor antagonist therapy. Consider hyperbaric oxygen |
| Joints | *Arthritis* | NSAIDs, anti-malarials, methotrexate, consider TNF inhibition* |
| Pulmonary | *Asymptomatic pulmonary hypertension* | Trial of steroids and cyclophosphamide, low dose aspirin and ACE inhibitors. Consider endothelin receptor antagonist (oral bosentan) |
| | *Symptomatic pulmonary hypertension* | Intravenous prostacyclin, angiotensin-converting enzyme inhibitors, anti-coagulation. Endothelin receptor antagonist (oral bosentan). Sildenafil trial. Heart–lung transplantation |
| | *Pleurisy* | NSAID or short course of prednisone—about 20 mg/day |
| Neurological | *Trigeminal neuropathy* | No effective therapy for numbness. Trial of an anti-epileptic (e.g., gabapentin) or tricyclic anti-depressant (e.g., nortryptiline) for pain |
| | *Aseptic meningitis* | Discontinue NSAIDs.† Short course of high-dose prednisone, about 60 mg/day |
| Renal | *Membranous glomerulonephropathy* | Mild—no treatment required<br>Progressive proteinuria—trial of ACE inhibitor; trial of low dose aspirin combined with dipyridamole.<br>Severe—trial of prednisone, 15-60 mg/day plus intermittent pulse cyclophosphamide or daily chlorambucil or rituximab |
| | *Nephrotic syndrome* | Steroids alone seldom effective. Low dose aspirin combined with dipyridamole to prevent thrombotic complications. ACE inhibitor to reduce protein loss. Trial of prednisone, 15-60 mg/day plus monthly pulse cyclophosphamide or rituximab<br>May require dialysis/transplantation |
| | *Scleroderma-like renal crisis* | ACE inhibitor |
| Cardiac | *Myocarditis*<br>*Pericarditis* | Trial of steroids and cyclophosphamide‡; avoid digoxin§<br>NSAID or short course of prednisone—about 20 mg/day Tamponade will require percutaneous or surgical drainage |
| | *Incomplete heart block* | Avoid chloroquine‖ |
| Gastrointestinal | *Dysphagia* | Mild—no treatment<br>With reflux—proton pump inhibitor. Consider Nissen fundoplication<br>Severe—Calcium channel antagonist, alone or in combination with an anti-cholinergic agent |
| | *Intestinal dysmotility* | Prokinetic agents such as metoclopramide, and erythromycin. Small bowel bacterial overgrowth—tetracycline, erythromycin |
| | *Heartburn/Dyspepsia* | Raise head of bed, discontinue smoking, lose weight, and avoid caffeine. H2 antagonists, $H^+$ proton pump blockers. Metoclopramide trial. Consider *H. Pylori* infection in recalcitrant cases |
| Muscle | *Myositis* | Acute onset/severe—prednisone, 60-100 mg/day<br>Chronic/low grade—prednisone, 10-30 mg/day¶<br>Consider methotrexate and/or IVIG in recalcitrant cases |
| Osteoporosis | *Osteoporosis* | Ca/Vit D supplements, estrogen replacement, or raloxifene Biphosphonates.# Nasal calcitonin. Carboxyl truncated PTH analogs such as hPTH-(1-34) |

*Has been associated with flares in MCTD and SLE.
†Sulindac and ibuprofen have been associated with a hypersensitivity aseptic meningitis.
‡Cardiotoxic at high doses.
§Predisposes to ventricular arrhythmias.
‖Predisposes to complete heart block.
¶Remain alert for steroid myopathy, aseptic necrosis of bone, and accelerated osteoporosis.

ACE, Angiotensin-converting enzyme; Ca, calcium; PTH, parathyroid hormone; TCA, tricyclic anti-depressant; Vit, vitamin.

some patients respond to a regimen of intravenous cyclophosphamide and corticosteroids.[140] Bosentan, an oral endothelium-1 antagonist, has been reported to improve dyspnea and to slow PAH progression in MCTD.[141] In the largest study of bosentan to date, 173 patients with World Health Organization (WHO) functional class II PAH were evaluated for a period of median exposure of 51 months. At the end of bosentan treatment, 77.8% of patients were in WHO functional class I/II, with a 4-year event-free survival rate of 79.5%; 20% of patients discontinued treatment

because of adverse events (mostly worsening of PAH and elevated liver enzymes).

Many of the problems that cause morbidity in overlap syndromes are intermittent and responsive to corticosteroids (e.g., aseptic meningitis, myositis, pleurisy, pericarditis, and myocarditis). On the other hand, nephrotic syndrome, Raynaud's phenomenon, deforming arthropathy, acrosclerosis, and peripheral neuropathies are usually steroid resistant. Many of the Scl-like gastrointestinal problems can be managed according to the usual practice in Scl, such as management of renal crisis with angiotensin-converting enzyme (ACE) inhibitors, Raynaud's phenomenon with calcium channel blockers, and gastrointestinal reflux disease with proton pump inhibitors.[137] Fibrotic lung disease is notoriously resistant to corticosteroids and immunosuppressives. There is some evidence that a new class of drugs, tyrosine kinase inhibitors (e.g., imatinib) may be effective in some patients.[142]

In patients with steroid-resistant thrombocytopenia, refractory myositis or hemolytic anemia, it is worth considering the use of intravenous gammaglobulin and/or rituximab.[143,144] Rituximab has also proved beneficial in some patients with severe anti-synthetase syndrome.[145] In patients with refractory disease, the use of these agents combined with plasmapheresis should be considered.[146] Successful autologous peripheral blood stem cell transplantation has been reported in a patient with refractory myositis and MCTD.[147] During the long term, concern usually mounts over the total corticosteroid burden and the possibility of inducing an iatrogenic steroid myopathy, nosocomial infection, aseptic necrosis of bone, or accelerated osteoporosis. Routine evaluation of bone mineral density is warranted to detect early presymptomatic osteoporosis and initiation of therapy with anti-resorptive agents. Unless contraindicated, all patients should take supplementary calcium and vitamin D. In patients requiring long-term corticosteroids, it would seem reasonable to use anti-malarials[148] or methotrexate[149] in an attempt to minimize the cumulative steroid burden. Anti-malarials should be used with caution in overlap patients with a fascicular or bundle branch block, because of the risk of causing a complete heart block[150] or an idiosyncratic hepatitis.[151] One should also remember that anti-malarial cardiotoxicity can mimic a cardiomyopathy with a prolonged QT(C).[152] Digitalis is relatively contraindicated in patients with myocarditis, because of the risk of inducing ventricular arrhythmias. As in SLE, the TNF inhibitor etanercept has been reported to exacerbate MCTD.[153] Patients with severe hand deformities may be helped by soft tissue release operations and selected joint fusions.

The management of pregnancy presents several special problems in patients with and in overlap CTDs. Doria has provided the following general advice[154]:

- Patients should be correctly informed on the risk of becoming pregnant.
- Pregnancies should be planned when the disease is in remission, because it increases the probability of successful maternal and fetal outcome.
- Patients should be regularly monitored during gestation and postpartum by a multidisciplinary team to include a rheumatologist, obstetrician, and neonatologist.
- In the case of disease relapse, an adequate treatment, even aggressive if necessary, should be recommended, because active disease can be more detrimental for the fetus than drugs.

There is often a tendency to assume that all patients with overlap CTDs should be on long-term corticosteroids. This mistake is compounded by the assumption that all medical problems in these patients are related to their underlying overlap CTDs. For instance, apparent flares of discomfort and pain in overlap CTDs may be caused by myofascial pain syndrome or fibromyalgia, and are thus unresponsive to corticosteroids. Similarly, the feeling of malaise and easy fatigability may be related to a reactive depression or the fact that the patient has become deconditioned. Premature atherosclerosis is now well recognized as a cause of increased morbidity and mortality in AICTDs.[155] All patients with overlap syndromes need ongoing evaluation for cardiovascular risk factors and appropriate advice and therapy for hypertension and hyperlipidemia. The management of patients with overlap CTDs requires continuing reassessment of an ever-changing pattern of clinical problems, and a constant alertness to the development of iatrogenic disease. As with any disease of unknown etiology, effective management of patients with overlap CTDs presents a constant and ever-evolving challenge.

## OUTCOME

The prognosis for overlap syndromes is often better than for the classic AICTDs. For instance, Troyanov reported on the follow up of 100 patients with idiopathic inflammatory myopathy. It was found that the long-term course after treatment with prednisone, with a dose/duration that initially resulted in good symptomatic improvement, was very different. All patients with PM (100%) and most patients with DM (92%) progressed to chronic myositis, whereas persistent muscle disease developed in only 58% of overlap patients.[4] In general, patients with Scl overlap syndromes have a better prognosis than patients with "pure" Scl. The tendency for chronic disease to develop in myositis first overlap patients was more common in patients with anti-synthetase and nucleoporin antibodies, and less common in patients with antibodies to -U1RNP, Pm-Scl, or Ku. Antibodies to TIF1-γ (p155/140) proteins in myositis are a risk factor for the development of cancer.[156] There is unequivocal evidence that patients with high-titer U1 RNP antibodies have a low prevalence of serious renal disease and life-threatening neurologic problems; in this sense MCTD can be favorably compared with classic SLE. However, not all patients with MCTD have a favorable prognosis. A follow-up of 280 MCTD patients seen between 1979 and 2011 reported a total of 22 deaths: nine deaths from pulmonary arterial hypertension, seven deaths from cardiovascular events, three deaths from thrombotic thrombocytopenic purpura, and three deaths from infections (Figure 86-18). Anti-endothelial antibodies and anti-cardiolipin antibodies were associated with increased mortality. Deceased patients were somewhat younger than survivors (35.5 ± 10.4 vs. 41.8 ± 10.7 yrs).[157] It is evident that the course of overlap syndromes is unpredictable. Many patients do follow a relatively benign course, but major organ involvement ultimately dictates the morbidity and mortality of the disease.

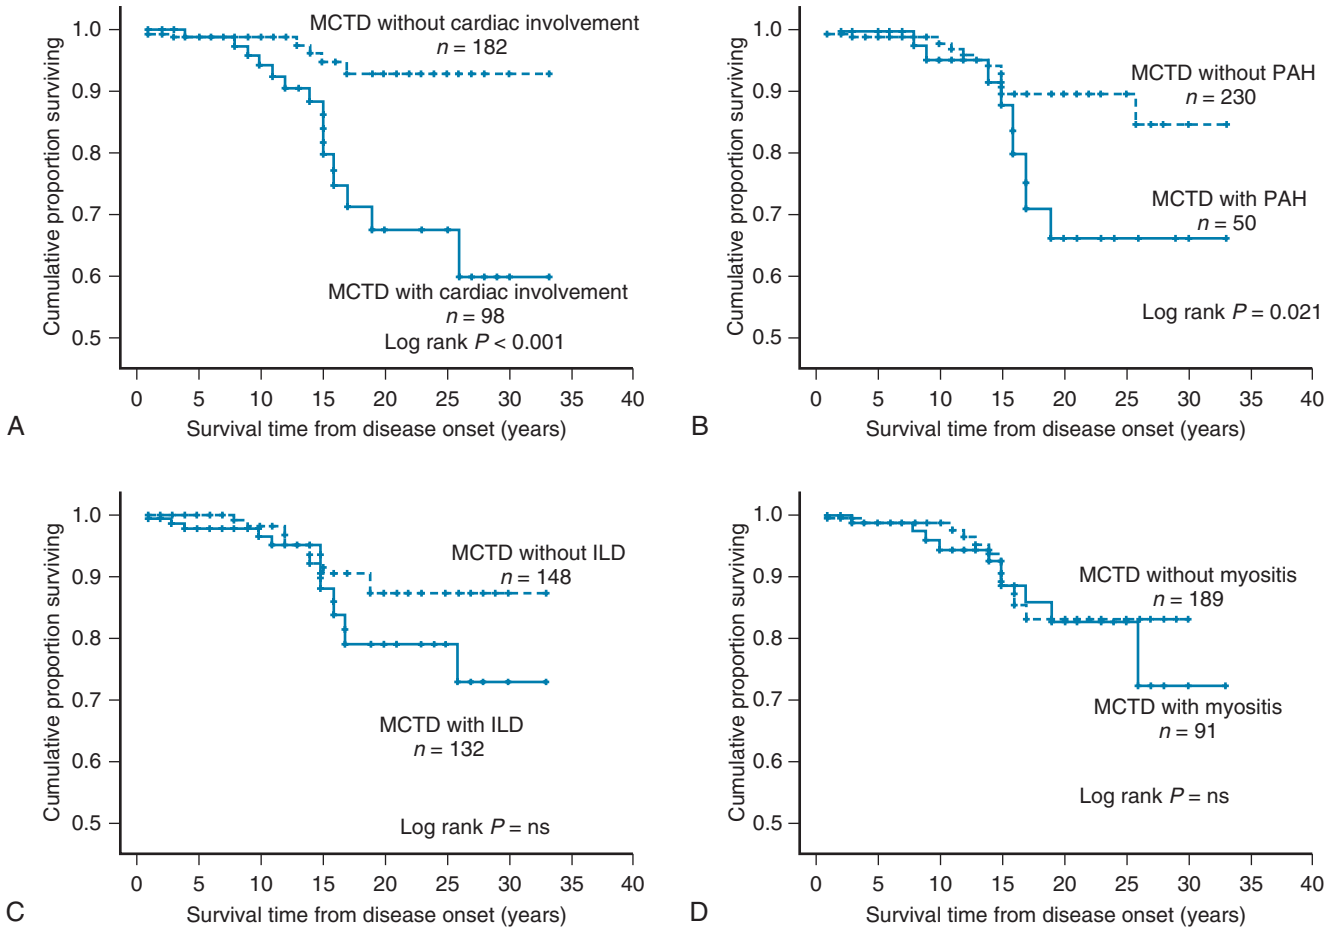

**Figure 86-18** Survival of patients with mixed connective tissue disease (MCTD) within various disease subgroups. **A,** Survival of patients with and without cardiovascular disease. **B,** Survival of patients with and without pulmonary arterial hypertension (PAH). **C,** Survival of patients with and without interstitial lung disease (ILD). **D,** Survival of patients with and without myositis. *(From Hajas A, et al: Clinical course, prognosis, and causes of death in mixed connective tissue disease.* J Rheumatol *40:1134–1142, 2013.)*

PART 13 VASCULITIS

CHAPTER 87

# Classification and Epidemiology of Systemic Vasculitis

John H. Stone

**KEY POINTS**

- Vasculitis is a heterogeneous group of disorders linked by the primary finding of inflammation within blood vessel walls. Nearly 30 forms of systemic vasculitis are currently recognized.
- Different forms of vasculitis have widely divergent profiles with regard to age, sex, and ethnicity.
- Vasculitides are classified first by the size of blood vessel involved—small (capillaries and postcapillary venules), medium (muscular arteries and arterioles), or large (the aorta and its major branches).
- Considerations in the clinical diagnosis of vasculitis include patient demographics, organ tropism, presence or absence of granulomatous inflammation, participation (or not) of immune complexes, finding of autoantibodies, detection of infections associated with some vasculitides, and the identification of other probable causes (e.g., drug-induced vasculitis syndromes).
- Associations between genes and vasculitis have been recognized increasingly in recent years. Progress also has been made in the area of gene-environment interactions.

## CLASSIFICATION

Few disorders in medicine are more challenging to diagnose and treat than the systemic vasculitides. These heterogeneous disorders are linked by the common finding of destructive inflammation within the walls of blood vessels. Current nomenclature and classification schemes recognize nearly 30 primary forms of vasculitis and several major categories of secondary vasculitis (e.g., other rheumatologic diseases, malignancy, and infection; Table 87-1). A widely accepted nomenclature scheme known as the Chapel Hill Consensus Conference (CHCC) was published in 2013.[1] During the past half century, however, a number of other classification schemes have been devised.[2] None—including the CHCC—has been entirely satisfactory because understanding of these conditions continues to evolve. Any vasculitis classification scheme will change as new information emerges.

Current classification schemes are understood best in light of their nosologic predecessors. The first "modern" case of systemic vasculitis was recognized in the 1860s by Kussmaul and Maier.[3] That case, which involved medium-sized, muscular arteries, has served as the reference point for classifying many subsequently recognized forms of vasculitis. Because of the importance of that first report in the understanding and classification of vasculitis, the case is described in detail here.

### First Modern Case: "Periarteritis Nodosa"

In 1866, Kussmaul and Maier reported the case of a 27-year-old tailor who died during a month-long hospital stay.[3,4] Upon presentation, the patient was strong enough to climb two flights of stairs to the clinic, but "afterward felt so weak that he immediately had to go to bed." He reported numbness on the volar aspect of his thumb and the two neighboring fingers on the right hand. During the ensuing days, "the general weakness increased so rapidly that he was unable to leave the bed, [and] the feeling of numbness also appeared in the left hand." Muscle paralysis progressed quickly: "Before our eyes, a young man developed a general paralysis of the voluntary muscles … [He] had to be fed by attendants, and within a few weeks was robbed of the use of most of his muscles."[3,4]

The patient's weakness, caused by vasculitic neuropathy (mononeuritis multiplex), was accompanied by tachycardia, abdominal pains, and the appearance of cutaneous nodules over his trunk. His death was described as follows: "He was scarcely able to speak, lay with persistent severe abdominal and muscle pains, opisthotonically stretched, whimpering, and begged the doctors not to leave him…. Death occurred … at 2 o'clock in the morning." At autopsy, grossly visible nodules were present along the patient's medium-sized arteries. Kussmaul and Maier[3] suggested the name "periarteritis nodosa" for this disease because of the apparent localization of inflammation to the perivascular sheaths and outer layers of the arterial walls, leading to nodular thickening of the vessels. The name was later revised to polyarteritis nodosa (PAN), to reflect the widespread arterial involvement of this disease and the fact that inflammation in PAN generally extends through the entire thickness of the vessel wall.[5,6]

### Polyarteritis Nodosa as a Reference Point

Several features of PAN make it a logical reference point for the classification of inflammatory vascular disease, in

ANCA, Anti-neutrophil cytoplasmic antibody.

addition to the fact that it was the cause of the first "modern" vasculitis case. Other forms of vasculitis can usually be differentiated from PAN through their contrasts to one or more of the following PAN characteristics:

- The general confinement of PAN to medium-sized vessels* as opposed to capillaries and postcapillary venules (small vessels) and the aorta and its major branches (large vessels)
- The exclusive involvement of arteries by PAN, with sparing of veins
- The tendency of PAN to form microaneurysms
- The absence of lung involvement in PAN
- The lack of granulomatous inflammation in PAN
- The absence of autoantibodies in PAN (e.g., anti-neutrophil cytoplasmic antibodies [ANCAs], anti-glomerular basement membrane [anti-GBM] antibodies, or rheumatoid factor)
- The association of some cases of PAN with hepatitis B virus (HBV) infection

*Vessel size overlap in vasculitis syndromes is subsequently acknowledged and discussed.

Constitutional symptoms: fever, weight loss, malaise, arthralgias/arthritis (common to vasculitides of all vessel sizes).

## Classification by Vessel Size

Because the causes of most forms of vasculitis are unknown, the most valid basis for classifying the vasculitides is the size of the predominant blood vessels involved. Under such classification schemes, the vasculitides are categorized initially by whether the vessels affected are large, medium, or small (see Table 87-1 and Figure 87-1). *Large* generally denotes the aorta and its major branches (and the corresponding vessels in the venous circulation in some forms of vasculitis, e.g., Behçet's disease).

*Medium* refers to vessels that are smaller than the major aortic branches yet still large enough to contain four elements: (1) an intima, (2) a continuous internal elastic lamina, (3) a muscular media, and (4) an adventitia. In clinical terms, medium-vessel vasculitis (see Table 87-1) is generally macrovascular (i.e., it involves vessels large enough to be observed in gross pathologic specimens or visualized by angiography). A useful way of thinking about this construct is that a large artery becomes a medium-sized artery when it penetrates a viscus. Thus, the renal artery is considered a large artery, but once it enters the kidney and separates into the smaller arcuate and interlobular arteries, these vessels are regarded as medium-sized arteries.

*Small-vessel* vasculitis, which incorporates all vessels below macroscopic disease, includes capillaries, postcapillary venules, and arterioles. Such vessels typically are all less than 500 μm in outer diameter. Because glomeruli may be viewed simply as differentiated capillaries, forms of vasculitis that cause glomerulonephritis are considered to be small-vessel vasculitides. Table 87-2 presents the typical clinical manifestations associated with small-, medium-, and large-vessel vasculitides.

Two points are relevant to a full understanding of the use of vessel size as the fundamental basis for classifying the

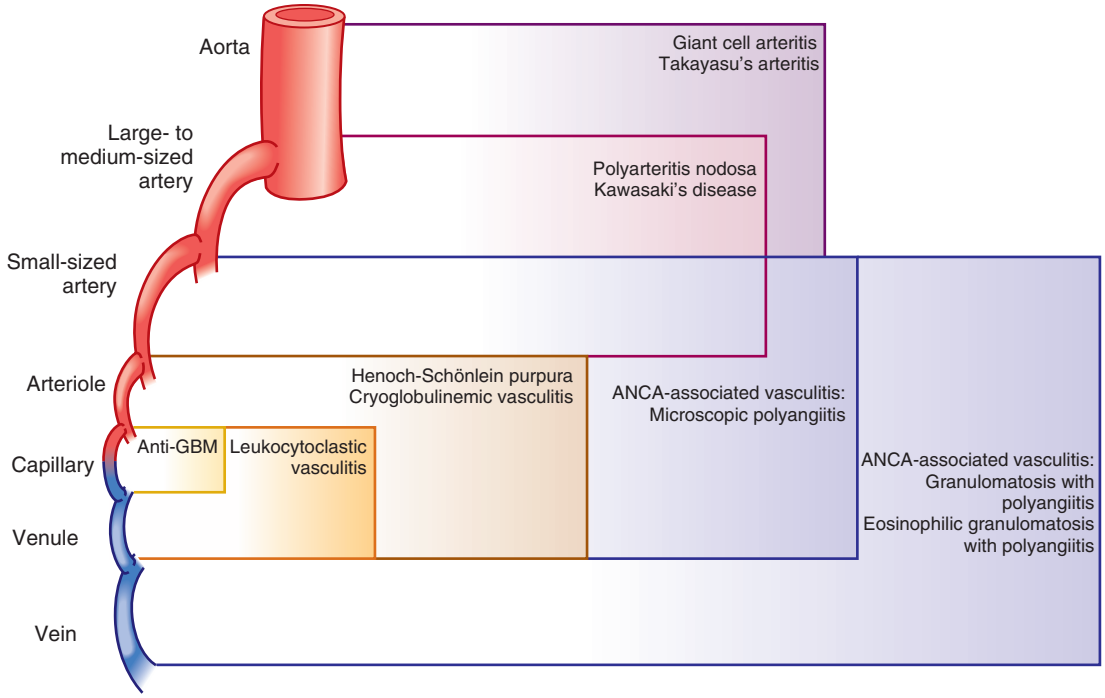

**Figure 87-1** Classification by blood vessel size. ANCA, Anti-neutrophil cytoplasmic antibody; GBM, glomerular basement membrane.

vasculitides. The first is that although large-vessel vasculitides affect larger arteries more often than do medium- or small-vessel vasculitis, medium-vessel vasculitis affects primarily medium-sized arteries, and small-vessel vasculitis primarily affects small arteries and other small vessels, all three major categories of vasculitides (large, medium, and small) can affect arteries of any size. It is crucial to recognize that both medium-vessel and even large-vessel vasculitides can affect small arteries. One transparent example of this phenomenon occurs in giant cell arteritis, the prototypical "large-vessel" vasculitis: the clinical manifestation of this disease most feared by patients—anterior ischemic optic neuropathy—is caused by small branches of the posterior ciliary and retinal arteries.

The second but related point pertains to the concept that some vasculitides are not easily pigeonholed as being primary large, medium, or small-vessel diseases. In fact, the most current CHCC nomenclature scheme includes a category termed "variable-vessel vasculitides." Classic variable vessel vasculitides are Behçet's disease and Cogan's syndrome. Despite the possibility of vessel size overlap within individual cases and the existence of forms of vasculitis that routinely affect vessels of variable size, the categorization of a patient's vasculitis as primarily large, medium, or small vessel remains enormously useful in focusing the differential diagnosis and initiating plans for treatment.

## Additional Considerations in Classification

Many other considerations are important in the classification of vasculitis (Table 87-3): (1) the patient's demographic profile (see the Epidemiology section), (2) the disease's tropism for particular organs, (3) the presence or absence of granulomatous inflammation, (4) the participation of immune complexes in disease pathophysiology, (5) the finding of characteristic autoantibodies in the patients' serum (e.g., ANCAs, anti-GBM antibodies, or rheumatoid factor), and (6) the detection of certain infections known to cause specific forms of vasculitis.

**TABLE 87-3** Considerations in the Classifications of Systemic Vasculitis

| Demonstration of a specific associated infection (hepatitis B or hepatitis C) |

ANCA, Anti-neutrophil cytoplasmic antibody; GBM, glomerular basement membrane.

The organ tropisms of these disorders are illustrated by the following examples. Granulomatosis with polyangiitis (GPA) classically involves the kidneys, upper airways, and lungs. In contrast, IgA vasculitis/Henoch-Schönlein purpura (HSP) often affects the kidneys, but never the nose or sinuses and almost never the lungs. In contrast to both of these forms of vasculitis, Cogan's syndrome is defined by the simultaneous occurrence of ocular inflammation caused by a small-vessel vasculitis (most often interstitial keratitis) and sensorineural hearing loss (and, in 10% of cases, a large vessel vasculitis). The histopathologic findings in these

*Sometimes granulomatous.

three disorders are equally distinctive, ranging from granulomatous inflammation of small to medium vessels (GPA) to IgA deposition in small vessels (HSP), to large vessel vasculitis centered on the adventitia (Cogan's syndrome).

The granulomatous features of some forms of vasculitis resemble chronic infections (e.g., infections caused by fungi or mycobacteria) or the inflammation induced by the presence of a foreign body. Granulomatous inflammation is more likely to be found in some organs (e.g., the lung) than in others (e.g., the kidney or skin). Some patients without evidence of granulomatous inflammation at early points in their courses later exhibit such features as their diseases unfold. Patients initially diagnosed with cutaneous leukocytoclastic angiitis or microscopic polyangiitis may be reclassified as having GPA if disease manifestations appear in new organs and granulomatous inflammation is found on biopsy specimens. Table 87-4 presents forms of vasculitis commonly associated with granulomatous inflammation.

Immune complexes are essential to the pathophysiology of some small- and medium- vessel vasculitides. Immune complex–mediated tissue injury does not produce a single unique clinical syndrome, but rather applies to many forms of vasculitis and overlaps with injuries caused by other immune mechanisms. Anti-GBM disease (Goodpasture's disease) is a unique form of immune complex disease in which the immune complexes form in situ rather than in the circulation.[7] Complexes of IgA1 are found in HSP. Immune complexes comprising IgG, IgM, complement components, and the hepatitis C virion characterize most cases of mixed cryoglobulinemia. HBV surface antigen/antibody complexes are present in the circulation and involved tissues of patients with HBV-associated vasculitis, a condition that often strongly resembles the "idiopathic" case of PAN described by Kussmaul and Maier. Rheumatoid factor and complement proteins are found within organs affected by rheumatoid vasculitis. The immune complex–mediated vasculitides are discussed further in Chapter 91.

In contrast, other small- and medium-vessel vasculitides such as GPA, microscopic polyangiitis, and eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome) are disorders associated with "pauci-immune" inflammation. "Pauci-immune" refers not to a lack of immunologic involvement in these disorders but rather to the relative absence (compared with the conditions regarded as immune complex–mediated) of immunoglobulin or complement deposition within diseased tissues. Many (but not all) patients with pauci-immune forms of vasculitis have ANCAs in their serum. Three decades before the description of ANCAs, Godman and Churg[8] observed pathologic links between these three entities, noting that the disorders "group themselves into a compass, [ranging from] necrotizing and granulomatous processes with angiitis, through mixed forms, to vasculitis without granulomata."

ANCAs (see Chapter 91) are directed against antigens that reside within the primary granules of neutrophils and monocytes.[9] Two types of ANCAs seem to be relevant to vasculitis: (1) ANCAs directed against proteinase 3 (PR3), a serine protease found within the primary granules of neutrophils and monocytes; and (2) ANCAs directed against myeloperoxidase and another serine protease found within the same granules. Although rigorous serologic assays for these antibodies are helpful in diagnosis, evidence for a primary etiologic role of these antibodies in human forms of pauci-immune vasculitis is still lacking. In contrast, anti-GBM antibodies have been proven to play a major role in the pathogenesis of Goodpasture's disease.[10] In rheumatoid arthritis (RA), systemic rheumatoid vasculitis occurs only in patients who are rheumatoid factor positive. Rheumatoid factor is believed to play an essential role in the immune complex nature of that disease complication. Finally, although the causes of most forms of vasculitis are unknown, several infections have been linked definitively with specific forms of these diseases (e.g., HBV with some cases of PAN and hepatitis C with mixed cryoglobulinemia).

## Historical Efforts at Classification and Nomenclature

For decades after this initial description of vasculitis, most forms of systemic inflammatory vascular disease were termed *periarteritis nodosa* because of the index case reported by Kussmaul and Maier. In the 1900s, two major factors led to the recognition of new forms of vasculitis: (1) the use of microscopy in the evaluation of pathologic specimens became routine, and (2) horse serum and sulfonamides came to be used in the treatment of many medical conditions. These new therapies frequently induced small-vessel vasculitides on the basis of immune complex deposition. Moreover, the serum sickness or "hypersensitivity" phenomena could be observed readily on tissue biopsy specimens through the microscope. In some cases, the histopathologic findings of hypersensitivity reactions were confused with periarteritis nodosa. The gradual recognition that these syndromes represented departures from the PAN described by Kussmaul and Maier spurred interest in the first classification scheme for necrotizing angiitis.

### The Zeek Classification

In 1952, Zeek[11] identified five major categories of necrotizing angiitis. The Zeek classification included (1) hypersensitivity angiitis, (2) allergic granulomatous angiitis (Churg-Strauss syndrome), (3) rheumatic arteritis (vasculitis associated with fulminant rheumatic fever), (4) periarteritis nodosa, and (5) giant cell arteritis. This classification scheme omitted several forms of systemic vasculitis that were known but had not yet been described in the English medical literature (e.g., GPA and Takayasu's arteritis). The number of diseases included in vasculitis classification and nomenclature schemes has continued to grow through

several subsequent attempts at defining more comprehensive systems for cataloging these diseases.

### The American College of Rheumatology Criteria for the Classification of Vasculitides

In 1990 the American College of Rheumatology (ACR) performed a study designed to establish criteria for the classification of vasculitis.[12,13] The study was designed to identify features that distinguished one form of vasculitis from others. An important caveat is that the study was *not* designed to establish criteria for diagnosis but rather to facilitate research by permitting the inclusion of similar types of patients in studies. Patients with giant cell arteritis, Takayasu's arteritis, PAN, GPA, eosinophilic granulomatosis with polyangiitis (Churg-Strauss Syndrome), HSP, and hypersensitivity vasculitis were included in this study.[14-20] The findings of the ACR study remain useful for the purposes of the study's original intention—the assurance of uniform inclusion criteria for patients in research studies.

The passage of time and the development of new insights pertaining to vasculitis have shown the need for updates to the ACR classification criteria. First, because the study was performed before the days of reliable and widely available assays for ANCAs, ANCA positivity was not considered as a possible classification criterion. Second, the ACR classification criteria study did not include microscopic polyangiitis as a separate disease but rather lumped such patients under the heading of PAN.[17] Third, the study did not define classification criteria for rarer forms of vasculitis such as Cogan's syndrome and Behçet's disease. Classification criteria for Behçet's disease were formulated in 1990 in a separate conference.[21]

### The First and Second Chapel Hill Consensus Conferences on Nomenclature

The first Chapel Hill Consensus Conference, convened in 1992, reviewed the nomenclature of systemic vasculitides.[22] Formal diagnostic criteria were not attempted, but definitions were created for 10 forms of vasculitis. In addition to the seven forms of vasculitis included in the ACR study, microscopic polyangiitis, Kawasaki's disease, and "essential" cryoglobulinemic vasculitis were defined. The CHCC emphasized the important role that ANCAs play in the diagnosis of small- to medium-vessel vasculitis and distinguished microscopic polyangiitis from classic PAN. The conference defined classic PAN as necrotizing inflammation of medium-sized or small arteries without glomerulonephritis.[22] Microscopic polyangiitis was defined as a necrotizing vasculitis with few or no immune deposits that (1) affects small blood vessels (e.g., capillaries, venules, or arterioles), (2) often includes glomerulonephritis and pulmonary capillaritis, and (3) is often associated with either myeloperoxidase (MPO)- or PR3-ANCA.

In the years following the first CHCC, it became clear that hepatitis C plays a major role in 90% of cases that formerly were termed *essential mixed cryoglobulinemia*. Some cases of this syndrome are not associated with hepatitis C infections, however, and probably have some other infectious etiology. Similarly, with the availability of the HBV vaccine, increasingly fewer cases of PAN are associated with this infection. Most PAN cases have no known cause. As emphasized by Churg,[23] cases of PAN currently termed *idiopathic* do not represent a single entity but almost certainly include several different disorders. Some of these disorders, as indicated by low serum complement levels and measurable immune complexes in the blood, are mediated by immune complex deposition. Others seem to be independent of this mechanism.

## Sources of Confusion in Classification

Two forms of vasculitis, now termed *microscopic polyangiitis* and *cutaneous leukocytoclastic angiitis*, have been consistent sources of confusion in vasculitis nosology. In the current understanding of systemic vasculitides, these two conditions are separate entities. Microscopic polyangiitis affects capillaries, veins, and arteries (in contrast to PAN) and is associated with ANCAs, most often directed against MPO, in at least 70% of cases.[24] Davson and colleagues[25] remarked on two forms of "periarteritis nodosa" with differential effects on the kidney—one with a predilection for medium-sized, muscular arteries and the other with a predilection for the smaller vessels, including the glomeruli. Davson and colleagues[25] termed this latter form *microscopic periarteritis nodosa*. Swayed by human and animal models of hypersensitivity that showed small-vessel disease involving the kidneys, lungs, and other organs,[26,27] Zeek chose to group microscopic periarteritis nodosa under the heading of *hypersensitivity vasculitis*.[11]

During the next several decades, hypersensitivity vasculitis came to refer to an immune complex–mediated small vasculitis of the skin that spared internal organs and often followed drug exposures.[14] The first CHCC[22] in 1992 recommended eliminating the term *hypersensitivity* altogether because evidence for hypersensitivity is lacking in many cases. Participants in the CHCC preferred the term *cutaneous leukocytoclastic angiitis* because of the disorder's typical confinement to the skin and the usual predominant cell type—the neutrophil. Although cutaneous leukocytoclastic angiitis can mimic the skin features of microscopic polyangiitis, cutaneous leukocytoclastic angiitis does not involve the kidneys, lungs, peripheral nerves, and other internal organs and is not associated with ANCAs.

Although *cutaneous leukocytoclastic angiitis* may be preferable to *hypersensitivity vasculitis* in describing small vessel vasculitis confined to the skin, the term fails to acknowledge the few cases in which lymphocytic infiltrates predominate, and the nonspecific term "lymphocytic vasculitis" is used. Thus, the term *hypersensitivity vasculitis* continues to have utility, particularly when the inciting event (e.g., a drug or infection) is known. Hypersensitivity vasculitis is discussed further in Chapter 91.

## EPIDEMIOLOGY

Developing an accurate definition of the epidemiology of vasculitis involves the following challenges: (1) the uncommon nature of some forms of vasculitis; (2) the frequent difficulties in making the correct diagnosis of vasculitis (and in distinguishing one form of vasculitis from another); (3) the fact that the causes of most types of vasculitis remain unknown; and (4) historical uncertainty with regard to the

**TABLE 87-5** Epidemiology of Select Forms of Vasculitis

| Disease | INCIDENCE | | Age/Sex/Ethnic Predispositions |
|---|---|---|---|
| | United States | Elsewhere | |
| Giant cell arteritis | 240/1 million | 240/1 million (Scandinavia) | Age >50 yr, mean age 72 yr; females 3:1/Northern European ancestry |
| Takayasu's arteritis | 3/1 million | 200-300/1 million (India) | Age <40 yr; females 9:1/Asian |
| Behçet's disease | 3/1 million | 3000/1 million (Turkey) | Silk Route countries |
| Polyarteritis nodosa | 7/1 million | 7/1 million (Spain) | Slight male predominance |
| Kawasaki's disease | 100/1 million* | 900/1 million (Japan) | Children of Asian ancestry |
| Granulomatosis with polyangiitis | 4/1 million | 8.5/1 million (United Kingdom) | Whites ≫ blacks |
| Henoch-Schönlein purpura | In children: 135-180/1 million; in adults: 13/1 million | | Only 10% of cases occur in adults |

*Among children younger than 5 years.
From Gonzalez-Gay MA, Garcia-Porrua C: Epidemiology of the vasculitides. *Rheum Dis Clin North Am* 27:729–750, 2001.

classification of these conditions. Nevertheless, in recent years, the epidemiology of some forms of vasculitis has been defined with reasonable precision. Table 87-5 presents the major epidemiologic features of several forms of systemic vasculitis.

## Geography

The epidemiologic features of systemic vasculitis vary tremendously by geography. This variation may reflect genetics, differences in environmental exposures dictated by continent and latitude, and the prevalence of other disease risk factors. Although Behçet's disease is rare in North Americans (affecting only approximately 1 in 300,000), the condition is substantially more common among inhabitants of countries that border the ancient Silk Route.[21,28] Similarly, although Takayasu's arteritis is rare in the United States—on the order of three new cases per 1 million people per year—the disease is reportedly the most common cause of renal artery stenosis in India, where the incidence may be 200 to 300 per million per year. Several studies indicate that the prevalence of giant cell arteritis in Olmsted County, Minnesota, is similar to that of Scandinavian countries, with an annual incidence rate of approximately 240 cases for every 1 million persons older than 50 years.[29] The similar prevalence calculations across these countries probably reflect shared genetic risk factors for this condition, because many of the current inhabitants of Olmsted County are descended from Scandinavia and northern Europe. On the basis of 2010 U.S. Census data, the prevalence of giant cell arteritis in the United States is on the order of 200,000 cases.

## Age, Sex, and Ethnicity

Age is an important consideration in the epidemiology of vasculitis. Among patients with Kawasaki's disease, 80% are younger than 5 years.[30] In contrast, giant cell arteritis virtually never occurs in patients younger than 50 years, and the mean age of patients with that disease is 72 years. Age also may affect disease severity and outcome. In HSP, most cases in children (with 90% of all cases occurring in children) have self-limited courses that resolve within several weeks. In adults, HSP has a higher likelihood of chronicity and a greater likelihood of a poor renal outcome.[31]

The distribution of sex varies across many forms of vasculitis. Takayasu's arteritis has an overwhelming tendency to occur in women (a 9:1 female-to-male ratio), a fact that presently has no explanation. Pauci-immune forms of vasculitis such as GPA occur in men and women with approximately equal frequencies, but some evidence exists for a female predominance in patients with the limited form of the disease and a male predominance among patients with severe GPA.[32] Behçet's disease tends to be more severe in male patients, with a greater frequency of advanced ocular disease.

Some forms of vasculitis have striking variations in tendencies to affect specific ethnic groups. For example, giant cell arteritis and GPA occur with an overwhelming predominance in white persons,[33-35] whereas Takayasu's arteritis and Kawasaki's disease have higher incidences in persons of Asian ancestry.

## Genetics

Although genetic risk factors are undoubtedly important in the susceptibility to some forms of vasculitis, familial cases are rare (with the exception of giant cell arteritis, as subsequently discussed). The rarity of familial cases in vasculitis indicates that the genetics of these disorders are polygenic and complex. The strongest link between any single gene and vasculitis is the association of human leukocyte antigen (HLA)-B51 with Behçet's disease. In Behçet's disease, 80% of Asian patients have the *HLA-B51* gene.[28] The prevalence of *HLA-B51* is significantly higher among patients with Behçet's disease in Japan than among control subjects without the disease (55% vs. <15%). Among the sporadic cases of Behçet's disease involving white patients in the United States, however, *HLA-B51* occurs in less than 15% of cases. In addition to increasing the risk of disease susceptibility in some patients, *HLA-B51* increases disease severity. Patients with this gene are more likely to have posterior uveitis, central nervous system involvement, or other severe manifestations.

Reports of familial aggregation in giant cell arteritis are common. Genetic studies have indicated roles for class II HLA alleles such as HLA-DRB1*0401 and HLA-DRB1*0101, although the specific associations have varied from study to study.[36,37] Other work indicates that certain

TNF microsatellite polymorphisms may contribute to disease susceptibility.[38]

The greatest progress in understanding the relationship of genetics to systemic vasculitis has come in the area of rheumatoid vasculitis. The contribution of the "shared epitope" found on class II HLA molecules (DR4) to the development of RA has been appreciated for two decades.[39] Possession of the shared epitope is now known to substantially increase the risk of extraarticular manifestations in RA including vasculitis, at least in Northern European populations. A gene dosage effect for extraarticular RA with severe organ manifestations has been noted; patients with two copies of shared epitope alleles have a substantially higher risk of extraarticular disease manifestations, many of which are mediated by vasculitis.[40] One study reported an association between rheumatoid vasculitis and 0401/0404.[41]

In a case-control study of patients who had severe extraarticular RA compared with patients with RA who did not have extraarticular disease manifestations, the presence of two HLA-DRB1*04 alleles encoding the shared epitope was associated with extraarticular RA (odds ratio [OR], 1.79; 95% confidence interval [CI], 1.04 to 3.08) and rheumatoid vasculitis (OR, 2.44; 95% CI, 1.22 to 4.89).[42] In a meta-analysis of HLA-DRB1 genotyping studies of patients with rheumatoid vasculitis,[43] rheumatoid vasculitis was found to be associated with the genotypes 0401/0401, 0401/0404, and 0401/0101.

An association between rheumatoid vasculitis and class I HLA molecules also has been reported. An analysis of 159 patients with severe extraarticular RA (46 of whom had vasculitis) and 178 patients with RA who did not have extraarticular disease reported a strong association between the HLA-C3 allele and vasculitis.[44] Among patients with vasculitis, the allele frequency of HLA-C3 was 0.41 compared with 0.20 in patients with RA who did not have extraarticular disease ($P < 0.001$). The OR for vasculitis in patients with HLA-C3 was 4.15 (95% CI, 2.14 to 8.08).

The association between HLA-C3 and vasculitis was not due to linkage disequilibrium with HLA-DRB1, suggesting that these two genetic risk factors operate through different pathways. HLA-C3 was a strong predictor of vasculitis in patients lacking HLA-DRB1*04 shared epitope alleles, suggesting that *HLA-C* and *HLA-DR* genes influence the RA disease process through different pathways. Linkage disequilibrium with other genes in the major histocompatibility complex (MHC) could not be excluded in this study, however.

In GPA, the allele frequency of a functional polymorphism, 620W, in the intra-cellular tyrosine phosphatase gene *PTPN22* was found to be increased significantly among ANCA-positive patients compared with healthy control subjects.[45] Analyses of families with multiple autoimmune disorders have identified this allele as a risk factor for type 1 diabetes, seropositive RA, systemic lupus erythematosus, and autoimmune thyroid disease. In GPA, the allelic association was particularly strong among patients with generalized disease (i.e., vasculitis involving the kidney, lung, eye, and peripheral nervous system).

A genome-wide association study confirmed a modest genetic component to the pathogenesis of ANCA-associated vasculitis.[46] The study, performed in a discovery cohort of 1233 United Kingdom patients with ANCA-associated vasculitis and 5884 control subjects and replicated in 1454 Northern European case patients and 1666 control subjects, demonstrated genetic distinctions between GPA and microscopic polyangiitis that were associated with ANCA specificity. The strongest genetic associations were with the type of ANCA (anti-PR3 vs. anti-myeloperoxidase) rather than with the clinical diagnoses of GPA versus MPA. Anti-PR3 ANCA was associated with HLA-DP and the genes encoding α(1)-anti-trypsin *(SERPINA1)* and PR3 *(PRTN3)* ($P = 6.2 \times 10[-89]$, $P = 5.6 \times 10[-12]$, and $P = 2.6 \times 10[-7]$, respectively). Anti-myeloperoxidase ANCA was associated with HLA-DQ: $P = 2.1 \times 10(-8)$.

## Environment

Several environmental and occupational exposures have been linked to the development of vasculitis. Medications and certain infections have well-known associations with vasculitides. As examples, antibiotics such as the penicillins and cephalosporins are common causes of hypersensitivity vasculitis (see Chapter 91), and virtually any medication can trigger this syndrome. Hepatitis B and C have well-recognized links to PAN and mixed cryoglobulinemia, respectively. Moreover, both medications and infections can serve as triggers for HSP.

Cigarette smoking is the strongest environmental exposure risk for RA, and smoking increases the risk of severe forms of RA such as rheumatoid vasculitis. In a case-control study of patients with recent-onset RA, the interactions among smoking, shared epitope genes, and antibodies to citrullinated proteins were studied.[47] A dose-dependent relationship between smoking and the occurrence of anti-citrullinated protein antibody (ACPA) was found. The presence of shared epitope genes was a risk factor for RA only among patients who were positive for ACPA. A major gene-environment interaction between smoking and *HLA-DR* SE genes was evident in the large subgroup of patients who possessed ACPAs: The combination of smoking history and double copies of shared epitope alleles increased the risk of RA 21-fold. Smoking may trigger RA-specific immune reactions to citrullinated proteins in the context of shared epitope genes.

Associations have been reported, but not confirmed, between exposure to inhaled silica dust and some types of pauci-immune vasculitis.[48] Precise definitions of the relationships between exposures and vasculitis are complicated by difficulties in obtaining reliable measurements of the levels of such exposures, the likelihood of recall bias among patients who are diagnosed with vasculitis, and the choice of appropriate control groups.

The epidemiologic differences among individual types of vasculitis raise compelling questions about the etiologies of these diseases. Ultimately, better insights into the pathogenesis of these conditions should explain these epidemiologic differences and facilitate the development of more refined classification schemes.

CHAPTER 88

# Giant Cell Arteritis, Polymyalgia Rheumatica, and Takayasu's Arteritis

David B. Hellmann

**KEY POINTS**

- Giant cell arteritis affects adults older than 50 years.
- The most common manifestations of giant cell arteritis are constitutional symptoms, headache, jaw claudication, and visual symptoms. Almost all untreated patients have an elevated erythrocyte sedimentation rate.
- The diagnosis of giant cell arteritis is usually confirmed by temporal artery biopsy.
- Early treatment of giant cell arteritis can prevent blindness.
- Polymyalgia rheumatica can occur by itself or with giant cell arteritis.
- Polymyalgia rheumatica responds to prednisone, 10 to 20 mg/day, whereas giant cell arteritis requires an initial dose of prednisone of approximately 60 mg/day.
- Takayasu's arteritis most frequently affects the aorta and its major branches in young women.

Giant cell arteritis (GCA) and polymyalgia rheumatica (PMR) are discussed together because they affect similar epidemiologic subsets of patients and often occur together in the same individual. Although GCA is a disease of older people and Takayasu's arteritis (TA) is a disease of younger people, their shared predilection for causing vasculitis of large arteries and their nearly identical histopathologic changes prompt their inclusion in the same chapter.

## GIANT CELL ARTERITIS AND POLYMYALGIA RHEUMATICA

### American College of Rheumatology Criteria

Classification criteria for the diagnosis of GCA have been proposed by the American College of Rheumatology (ACR) (Table 88-1).[1] Three classification schemes have been proposed for PMR (Table 88-2).[2-4] The provisional criteria for 2012 were developed in part to incorporate information from ultrasound evaluation.

### Definitions

#### Giant Cell Arteritis

GCA is the most common form of systemic vasculitis in adults.[5] The disease affects primarily the extracranial branches of the carotid artery in patients older than 50 years. The most feared complication of GCA is irreversible loss of vision. Because the cause of GCA is unknown, various names—including *temporal arteritis*, *cranial arteritis*, and *granulomatous arteritis*—have been used to highlight different salient features.[6] All the names for this disease have both merits and shortcomings. The designations *temporal arteritis* or *cranial arteritis*, for example, convey how frequently the temporal arteries or other cranial arteries are involved but fail to capture GCA's more widespread nature. Although the terms *granulomatous arteritis* and GCA recognize an important pathologic finding, this focus is undeserved because giant cells are absent in approximately half of the cases, and may be present in other forms of vasculitis. With no perfect name available, this chapter bows to convention and refers to this disease as *giant cell arteritis*.

### Polymyalgia Rheumatica

*Polymyalgia rheumatica*, a term suggested by Barber, is a syndrome characterized by aching in the proximal portions of the extremities and torso. Because no specific diagnostic tests or pathologic findings exist, PMR is defined by its clinical features. The features included in most definitions of PMR are as follows (1) aching and morning stiffness lasting half an hour or longer in the shoulder, hip girdle, neck, or a combination; (2) duration of these symptoms for 1 month or longer; (3) patient age older than 50 years; and (4) laboratory evidence of systemic inflammation such as an elevated erythrocyte sedimentation rate (ESR).[2] Some definitions also include a rapid response to small doses of glucocorticoids, such as prednisone 10 mg/day.[7] The presence of another specific disease other than GCA, such as rheumatoid arthritis (RA), chronic infection, polymyositis, or malignancy excludes the diagnosis of PMR.

### Epidemiology

The incidence of GCA varies widely in different populations, from less than 0.1 per 100,000 to 77 per 100,000 individuals aged 50 years and older.[5,8-12] The greatest risk factor for GCA is aging: the disease almost never occurs in individuals younger than 50 years, and its incidence rises steadily thereafter. The average age at diagnosis has risen during the past half century, from 74.7 years in the 1950s to 79.2 years at present.[13] Nationality, geography, and race are also important. The highest incidence is found in Scandinavians and in Americans of Scandinavian descent. The lowest incidence of GCA is reported in Japanese, northern

Supplemental images available on the accompanying ExpertConsult website.

**TABLE 88-1** American College of Rheumatology Classification Criteria for Giant Cell Arteritis

| Criterion | Definition |
|---|---|
| Age at disease onset ≥50 yr | Development of symptoms or findings beginning at age 50 yr or older |
| New headache | New onset or new type of localized pain in the head |
| Temporal artery abnormality | Temporal artery tenderness to palpation or decreased pulsation, unrelated to arteriosclerosis of cervical arteries |
| Elevated ESR | ESR ≥50 mm/hr by the Westergren method |
| Abnormal artery biopsy | Biopsy specimen with artery showing vasculitis, characterized by a predominance of mononuclear cell infiltration or granulomatous inflammation, usually with multinucleated giant cells |

*For purposes of classification, a patient with vasculitis is said to have giant cell (temporal) arteritis if at least three of these five criteria are present. The presence of any three or more criteria yields a sensitivity of 93.5% and a specificity of 91.2%.

ESR, Erythrocyte sedimentation rate.

From Hunder GG, Bloch DA, Michel BA, et al: The American College of Rheumatology 1990 criteria for the classification of giant cell arteritis. *Arthritis Rheum* 33:1125, 1990.

Indians, and African-Americans. In Western Europe, GCA is more common in the northern latitudes than the southern. The diagnosis of GCA has been increasing during the past 20 to 40 years, possibly because of greater physician awareness.[5,8] Some studies have reported seasonal variations and clustering of cases, with peaks approximately 7 years apart.[8,11] The prevalence of GCA in Olmsted County, Minnesota, home to many Scandinavian immigrants, is 200 per 100,000 population aged 50 years or older. Autopsy studies suggest that GCA may be more common than is clinically apparent. Östberg[14] found arteritis in 1.6% of 889 postmortem cases in which sections of the temporal artery and two transverse sections of the aorta were examined.

Genetic susceptibility to GCA was initially suggested by reports of GCA in families[15] and, more recently, by studies demonstrating an association with genes in the class II human leukocyte antigen (HLA) region.[16] Sixty percent of GCA patients have HLA-DRB1*04 haplotype variants, which have a common sequence motif in the second hypervariable region of the B1 molecule.[16] This motif differs from the one associated with RA.[16] The low prevalence of these alleles in African-Americans might explain why GCA is uncommon in this population. To date, GCA is the form of

**TABLE 88-2** Diagnostic* and Classification Criteria for Polymyalgia Rheumatica

| | | |
|---|---|---|
| **Diagnostic Criteria of Chuang and Colleagues (1982)** | | |
| Age 50 yr or older | | |
| Bilateral aching and stiffness for 1 month or more and involving two of the following areas: neck or torso, shoulders or proximal regions of the arms, and hips or proximal aspects of the thighs | | |
| ESR >40 mm/hr | | |
| Exclusion of all other diagnoses except giant cell arteritis | | |
| **Diagnostic Criteria of Healey (1984)** | | |
| Pain persisting for at least 1 mo and involving two of the following areas: neck, shoulders, and pelvic girdle | | |
| Morning stiffness lasting >1 hr | | |
| Rapid response to prednisone (≤20 mg/day) | | |
| Absence of other diseases capable of causing the musculoskeletal symptoms | | |
| Age older than 50 yr | | |
| ESR >40 mm/hr | | |
| **Classification Criteria of Dasgupta and Colleagues (2012)** | | |
| Age 50 years or older, bilateral shoulder aching, and abnormal C-reactive protein and/or ESR† | | |
| | **Points Without US (0-6)** | **Points With US‡ (0-8)** |
| Morning stiffness duration >45 min | 2 | 2 |
| Hip pain or limited range of motion | 1 | 1 |
| Absence of rheumatoid factor or anti-citrullinated protein antibody | 2 | 2 |
| Absence of other joint involvement | 1 | 1 |
| At least one shoulder with subdeltoid bursitis and/or biceps tenosynovitis and/or glenohumeral synovitis (either posterior or axillary) and at least one hip with synovitis and/or trochanteric bursitis | Not applicable | 1 |
| Both shoulders with subdeltoid bursitis, biceps tenosynovitis or glenohumeral synovitis | Not applicable | 1 |

*For each set of criteria, all the findings must be present for polymyalgia rheumatica to be diagnosed.

†A score of 4 or more is categorized as polymyalgia rheumatica in the algorithm without ultrasound (US), and a score of 5 or more is categorized as polymyalgia rheumatica in the algorithm with US.

‡Optional ultrasound criteria.

ESR, Erythrocyte sedimentation rate.

Reproduced with permission.

systemic vasculitis most closely associated with class II HLA genes. Susceptibility to GCA and PMR has also been associated with polymorphisms of genes for TNF, intercellular adhesion molecules, and interleukin (IL)-18.[5]

The existence of environmental risk factors has been suggested by the geographic clustering of GCA cases. Smoking increases the risk for GCA sixfold in women.[17] Circumstantial evidence links the development of GCA to a variety of infectious agents including *Mycoplasma pneumoniae*, varicella-zoster virus, parvovirus B19, and parainfluenza virus type I.[11,12] The results of examining temporal artery biopsy specimens with polymerase chain reaction methods to detect parvovirus B19 or herpesvirus DNA have been negative or inconsistent.[18] The reported association between GCA and *Chlamydia pneumoniae* infection has not withstood close scrutiny.[19] One study, published only in abstract form in 2012, identified a *Burkholderia* bacterium in 9 of 10 temporal arteries in GCA but in 0 of 11 controls.[20] Sex and health status also influence the development of GCA. Women are affected approximately twice as often as men.[11] Having diabetes reduces the risk of GCA by 50% in women.[2] Although patients with GCA have an increased risk of developing thoracic aortic aneurysms, they do not have overall higher mortality rates.[11]

PMR is two to three times more common than GCA.[5,9,10,21] In Olmsted County, Minnesota, 245 cases of PMR were diagnosed during the 22-year period from 1970 through 1991, providing an average annual incidence rate of 52.5 cases per 100,000 individuals aged 50 years or older.[21] The prevalence of PMR (active plus remitted cases) was approximately 600 per 100,000 individuals aged 50 years and older.[21] PMR is associated with the same *HLA-DR4* genes as GCA.[16,22]

## Etiology, Pathology, and Pathogenesis

The causes of GCA and PMR are unknown. Because pathologic studies have provided important clues to the pathogenesis, they are discussed first.

In GCA, inflammation is found most often in medium-sized muscular arteries that originate from the arch of the aorta.[11,14,23,24] The inflammation tends to affect the arteries in a segmental fashion (possibly leading to "skip lesions" within arteries), but long portions of arteries may be involved.[25] In patients who died during the active phase of GCA, the greatest frequency of severe involvement was noted in the superficial temporal arteries, vertebral arteries, and ophthalmic and posterior ciliary arteries.[26] The internal carotid, external carotid, and central retinal arteries were affected somewhat less frequently.[26] In other post-mortem studies, lesions were commonly found in the proximal and distal aorta and internal and external carotid, subclavian, brachial, and abdominal arteries.[14] Because GCA affects vessels with an internal elastic lamina and vasa vasorum, and because intracranial arteries lose these structures after penetrating the dura, it is not surprising that GCA rarely involves intracranial arteries.[26-28] In some patients with GCA, follow-up biopsy or autopsy surveys showed the persistence of mild chronic inflammation, even though symptoms had resolved.[2]

Early in the disease, collections of lymphocytes are confined to the region of the internal or external elastic lamina or adventitia. The inflammation may be limited to the vasa vasorum in some cases.[3] Intimal thickening with prominent cellular infiltration is a hallmark of more advanced cases. In heavily involved areas, all layers are affected (Figure 88-1). Transmural inflammation of portions of the arterial wall (including the elastic laminae) and granulomas containing multinucleated histiocytic and foreign body giant cells, histiocytes, lymphocytes (which are predominantly $CD4^+$ T cells), and some plasma cells and fibroblasts are found.[24,29,30] Eosinophils may be seen, but polymorphonuclear leukocytes are rare. Thrombosis may develop at sites of active inflammation; later, these areas may recanalize. The inflammatory process is usually most marked in the inner portion of the media adjacent to the internal elastic lamina. Fragmentation and disintegration of elastic fibers occur, closely associated with an accumulation of giant cells (Figure 88-2; see supplemental Figure 88-1 at ExpertConsult.com). However, giant cells are seen in only approximately half of routinely examined specimens; therefore, they are not required to make the diagnosis if other features are compatible. In contrast to some other forms of systemic vasculitis (e.g., polyarteritis nodosa, microscopic polyangiitis, granulomatosis with polyangiitis [GPA]), fibrinoid necrosis is rarely, if ever, observed in GCA.[3]

**Supplemental Figure 88-1** Aortitis in giant cell arteritis. Media of aorta is infiltrated with giant cells and mononuclear inflammatory cells (hematoxylin and eosin, ×40). *(Courtesy Dr. Gene Hunder.)*

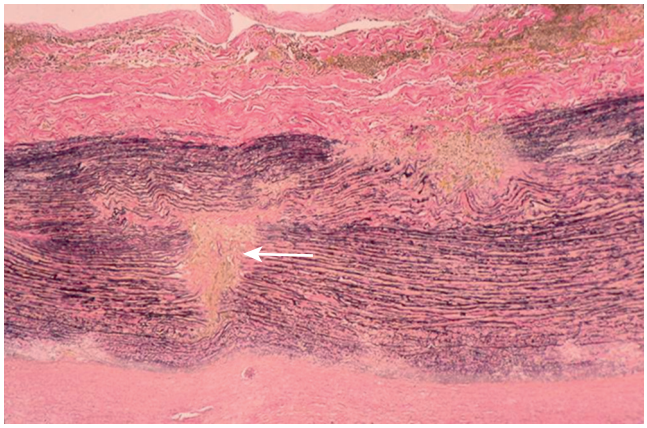

**Figure 88-2** Giant cell arteritis involving the proximal aorta in a patient who died of a ruptured ascending aorta. This section of the ascending aorta is distal to the ruptured portion and shows destruction of elastic fibers *(arrow)* (elastic van Gieson stain, ×64). Neighboring sections stained with hematoxylin and eosin showed infiltrations of mononuclear leukocytes in the areas of disrupted fibers.

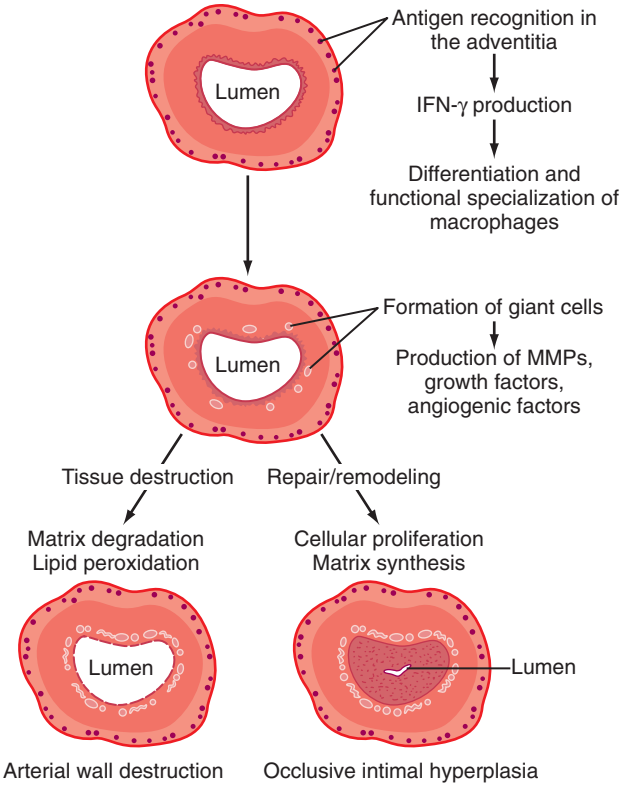

**Figure 88-3** Proposed model for the pathogenesis of giant cell arteritis. IFN, Interferon; MMPs, matrix metalloproteinases.

Immunohistochemical studies demonstrate inflammatory changes that are specific for each layer of the affected artery.[12, 24, 30-33] Dendritic cells, which can present antigen and activate T cells, are found in the adventitia, along with two separate lineages of $CD4^+$ T cells: (1) T helper (Th)1 cells that secrete interferon (IFN)-γ and IL-2 and (2) Th17 cells that secrete IL-17 family members including IL-17A.[34-36] The adventitial T cells show evidence of clonal expansion. The adventitia is also infiltrated with macrophages that secrete IL-1, IL-6, and transforming growth factor (TGF)-β. The media is populated mostly by macrophages that, in contrast to those in other layers, produce matrix metalloproteinases and oxygen-free radicals. Closer to the intima, the macrophages secrete nitric oxide and unite to form syncytia—the giant cells—which produce platelet-derived growth factor (PDGF) and substances that stimulate intimal proliferation.[24,37]

Although the gross appearance of arteries in patients with PMR is usually healthy, immunohistochemical studies of apparently uninvolved temporal arteries reveal increases of the same macrophage-related inflammatory cytokines found in GCA.[24] The T cell cytokine IFN-γ is abundantly expressed in GCA and is absent in arteries from patients who have only PMR. Pathologically, relatively little else has been found in the arteries of patients with PMR. Granulomatous myocarditis and hepatitis have been noted.[38] Muscle biopsies may be normal or show nonspecific type II muscle atrophy. However, a number of reports have shown the presence of lymphocytic synovitis in the knees, sternoclavicular joints, and shoulders and evidence of a similar reaction in sacroiliac joints.[39,40] Synovitis (mostly subclinical) was shown in bone scans demonstrating an increased uptake of technetium pertechnetate in the joints of 2 of 25 patients with PMR.[39] More sensitive studies that used MRI and ultrasonography have convincingly demonstrated that in PMR, the principal foci of inflammation are the bursae surrounding the shoulder more than the glenohumeral joint itself.[6] Sera from patients with GCA, PMR, or both demonstrate evidence of systemic inflammation, with increased levels of circulating immune complexes during active disease[41] and elevated levels of IL-6 and IL-1.[8]

These observations, together with the results from experiments in which temporal arteries from patients with GCA have been implanted into mice with severe combined immunodeficiency (SCID), suggest that GCA results from an adaptive immune response in the wall of an artery.[24,35,42,43] In this model, (Figure 88-3) the key initiating event is activation of dendritic cells located in the adventitia, the only arterial layer normally penetrated by the vasa vasorum. In large- and medium-sized arteries, immunohistochemical studies reveal that the dendritic cells in temporal arteries have a specific phenotype and express fascin and CD11c.[24,34] Dendritic cells express Toll-like receptors (TLRs) that normally serve as sentinels, monitoring for any immunologic breach of the adventitia.[44] In GCA, activation of TLRs on dendritic cells appears to be the initial triggering event.[34,44,45] Of the many different types of TLRs, TLR-2 and TLR-4 might be the most important in GCA. Although the exact trigger of the adaptive immune response in GCA is not known, experiments in the GCA-SCID mouse model have shown that blood-borne lipopolysaccharide serves as an effective TLR ligand in temporal arteries. Other constituents of microorganisms or some self-antigens (e.g., oxidized lipids) might also be TLR ligands that activate the arterial dendritic cells.

Once its TLRs have been engaged, dendritic cells differentiate from the resting to the active state and release cytokines such as IL-6 and IL-18, which recruit, activate, and retain $CD4^+$ T cells in the blood vessel. The crucial role

of dendritic cells in activating T cells and maintaining vasculitis has been demonstrated in the GCA-SCID mouse model. Depleting the dendritic cells markedly reduces the T cell infiltrate and suppresses the vasculitis. As noted, two separate populations of $CD4^+$ T cells become activated and expand: IFN-γ producing Th1 cells and IL-17 producing Th17 cells. IFN-γ causes macrophages to migrate, differentiate, and form granulomas.[36,44] Production of matrix metalloproteinases and lipid peroxidation agents by macrophages in the media results in the destruction of elastic laminae. The vessel attempts to counter the tissue destruction by elaborating a variety of growth factors including PDGF, vascular endothelial growth factor (VEGF), and TGF-β, which prompt smooth muscle cells in the media to revert from a contractile phenotype to a secretory one and migrate to the intima. Proliferation of the intimal smooth muscle cells results in occlusion of the lumen.[24,34]

PMR appears to result from a similar but less intense adaptive immune response in blood vessels (as evidenced by the in situ production of many inflammatory cytokines). According to this model, both PMR and GCA begin with the activation of dendritic cells at the adventitia-media border.[34,45] However, the distinguishing feature of PMR is the absence of T cells producing IFN-γ. Without IFN-γ to stimulate the recruitment and differentiation of macrophages, the level of arterial inflammation in PMR remains subclinical. Thus, the development of GCA appears to require both vascular dendritic cell activation and a disease-inducing repertoire of T cells.[24,34,45] The constitutional symptoms of PMR and GCA are attributed to the high levels of inflammatory cytokines (e.g., IL-1 and IL-6) found in the sera. Whether these serum cytokine elevations result from blood vessel inflammation alone or from some other source of inflammation is not yet clear. The attractiveness of this model is increased by its ability to explain why subsets of clinical features occur together.

## Clinical Features

The mean age at onset of GCA and PMR is approximately 79 years, with a range of approximately 50 to 90 years of age.[11,13] Younger patients with PMR have been described occasionally. Women are affected approximately twice as often as men.[21] Although the onset of the disease is usually insidious, typically evolving during weeks or months, in one-third of cases, the disease begins so abruptly that some patients recall the very day they became ill.[11,38]

### Giant Cell Arteritis

**Classic Manifestations.** The most common manifestations of GCA are constitutional symptoms, headache, visual symptoms, jaw claudication, and PMR[11] (Table 88-3). Almost all patients experience one or more constitutional symptoms including fatigue, weight loss, malaise, and fever.

Besides constitutional symptoms, headache is the most common symptom in GCA, being present in nearly three-quarters of patients.[46] The pain is typically described as boring in quality, of moderate severity, and most commonly appreciated in the temporal area. However, the description of the headache varies enormously. It can be mild to so severe that the patient seeks immediate relief by going to the emergency department. The pain may localize to any part of the skull, including the occiput (because of involvement of the occipital artery).[11,14] The most consistent characteristic is that the patient experiences the headache as something new and unusual. In untreated patients, the headache may subside over weeks, even though the disease activity continues. Often, the headache of GCA is not associated with any particular findings on physical examination. Abnormalities of the temporal artery—including enlargement, nodular swelling, tenderness, or loss of pulse—manifest in only approximately half of patients (Figure 88-4). Some patients note tenderness of the scalp, which can be aggravated by brushing or combing the hair.

Visual symptoms are common in GCA, especially loss of vision and diplopia. Vision loss can be unilateral or (less

| Diplopia | 9 |

Modified from Smetana GW, Shmerling RH: Does this patient have temporal arteritis? *JAMA* 287:92, 2002. Data from a review of 2475 patients reported in the literature.

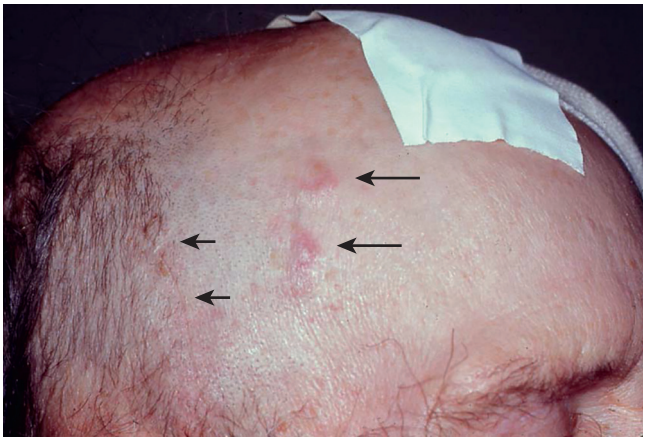

**Figure 88-4** Giant cell arteritis (GCA) involving the temporal artery. Short segments of curved artery were erythematous and tender *(long arrows)*. The bandage on the scalp covers a similar artery that was biopsied and showed GCA. A previous biopsy specimen of a proximal segment of the right temporal artery, which was normal on physical examination, was normal histologically. The faint scar from that biopsy can be seen above and anterior to the right ear *(short arrows)*.

commonly) bilateral, transient or permanent, and partial or complete.[47] Vision loss that lasts more than a few hours usually does not reverse. Loss of vision often reflects an anterior ischemic optic neuropathy caused by occlusive arteritis of the posterior ciliary artery, the chief blood supply to the head of the optic nerve. The posterior ciliary artery is a branch of the ophthalmic artery (which derives, in turn, from the internal carotid artery). Less frequently, vision loss in GCA stems from a retinal artery occlusion. Regardless of the site of the culprit lesion, vision loss in GCA is usually profound, with more than 80% of patients unable to see hand waving.[47] Vision loss is less likely to develop in GCA patients who are seen with fever or other systemic symptoms.[48,49] One possible explanation of this protective effect of fever and other systemic manifestations is that patients with prominent systemic inflammation demonstrate more extensive angiogenesis in temporal artery biopsies.[7] The angiogenesis associated with increased inflammation may result in the development of collateral circulation that reduces the chance of ischemic events.[7]

The early funduscopic appearance in the setting of blindness caused by anterior ischemic optic neuropathy is that of ischemic optic neuritis: slight pallor and edema of the optic disc, with scattered cotton-wool patches and small hemorrhages[47] (Figure 88-5). Later, optic atrophy occurs. Rarely, blindness may be the initial symptom; however, it tends to follow other symptoms by several weeks or even months. Ophthalmoscopic examination in patients without eye involvement is generally normal. In most reports, the incidence of blindness is 20% or less.[7,47,50] In a series of 245 patients from the modern era, 34 (14%) had some permanent loss of vision.[50] In 32 of these patients, the deficit developed before glucocorticoid therapy was begun; in the other 2, vision loss occurred after therapy was started. Vision loss progressed in 3 of the 32 after therapy was initiated, and it improved in 5 patients. At 5 years' follow-up, among the patients who had visual deficits caused by GCA at the time glucocorticoids were started, the risk of additional loss of vision was 13% during the follow-up period. If no loss had occurred at the beginning of glucocorticoid therapy, there was only a 1% risk of new loss of vision during the subsequent 5 years.

Another potential ocular complication of GCA is ophthalmoplegia. Diplopia usually results from ocular motor nerve palsies caused by ischemia and usually resolves after therapy is started. Oculomotor nerve involvement in GCA usually spares the pupil.[47] Rarely, arterial lesions cause infarction of the occipital cortex and vision loss.

Intermittent claudication may occur in the muscles of mastication (jaw claudication), the extremities, and, occasionally, the muscles of the tongue or those involved in swallowing.[11] In the jaw muscles, the discomfort is noted, especially when chewing meat, and may involve the muscles on one side of the mandible more than those on the other. In some instances, facial artery involvement results in spasm of the jaw muscles. More marked vascular narrowing may lead to gangrene of the scalp or tongue.

**Atypical Manifestations.** Approximately 40% of patients are seen with disease manifestations that are considered atypical[35,51-53] (Table 88-4). In these patients, headache, jaw claudication, visual symptoms, and PMR do not occur or are less prominent.

Fever occurs in as many as 40% of patients with GCA, but it is usually low grade and overshadowed by other classic symptoms. However, 15% of GCA patients may present with fever of unknown origin (FUO) in which the temperature spikes are high, dominating the clinical picture.[7,38] Although GCA causes only 2% of all cases of FUO, it is responsible for 16% of all such fevers in individuals older than 65 years.[38] Approximately two-thirds of patients experience shaking, chills, and drenching sweats, features often attributed to infection or malignancy. The median

temperature is 39.1° C, and the maximum 39.8° C. The white blood cell count in GCA-induced FUO is usually normal or nearly so (at least before the initiation of prednisone).

Neurologic problems occur in approximately 30% of patients.[1,54] These are diverse, but most common are neuropathies and transient ischemic attacks or strokes. Hemiparesis or brain stem events are to the result of narrowing or occlusion of the carotid or vertebrobasilar artery. GCA preferentially involves the posterior circulation: the 3:2 ratio of anterior to posterior strokes and transient ischemic attacks seen in the normal population reaches nearly 1:1 in patients with GCA.[55] Delirium, reversible dementia, and myelopathy have also been reported. However, the assignment of an exact cause to ischemic central nervous system events is often challenging, given the older population in which GCA occurs. The neuropathies of GCA include mononeuropathies and peripheral polyneuropathies and may affect the upper or lower extremities. Presumably, they are secondary to the involvement of nutrient arteries, but little pathologic documentation is available. Among the vasculitides, GCA has a nearly unique propensity for involving the C5 nerve root, resulting in loss of shoulder abduction.[27] Mononeuropathies affecting the hands and feet, so typical of polyarteritis and other forms of vasculitis, develop less often in patients with GCA.

Prominent respiratory tract symptoms occur in approximately 10% of patients.[56] These include cough with or without sputum, sore throat, and hoarseness. When these symptoms are severe or an initial manifestation of GCA, they may direct the attention of the examining physician away from the underlying arteritis. Vasculitis may induce these symptoms by causing ischemia or hyperirritability of the affected tissues. Otolaryngeal manifestations of GCA include throat pain, dental pain, tongue pain, glossitis, and ulceration or infarction of the tongue.[56,57]

Clinical evidence of large artery involvement occurs in 10% to 15% of patients at presentation, and in as many as 27% eventually.[3,40,58] Positron emission tomography (PET) studies with fluorodeoxyglucose (FDG) revealed that subclinical involvement of large arteries occurs in the vast majority of GCA patients. One PET study, for example, showed that 88% of 35 patients had increased FDG uptake in large arteries, with subclavian involvement in 7% and aortic involvement in 54%.[59]

Generally, clinically evident disease can be divided into early (within a year of diagnosis) and late (years after diagnosis) stages. Usually, early disease consists chiefly of large artery stenosis resulting in upper extremity claudication; bruits over the carotid, subclavian, axillary, and brachial arteries; absent or decreased pulses in the neck or arms; and Raynaud's phenomenon (Figure 88-6).[58] Angiographic features that suggest GCA are smooth-walled arterial stenoses or occlusions alternating with areas of normal or increased caliber in the absence of irregular plaques and ulcerations, located especially in the carotid, subclavian, axillary, and brachial arteries. Late disease most frequently involves thoracic aortic aneurysm.[58] The tendency for aneurysm to develop late was confirmed in one series of 41 patients in which the average time between diagnosis of GCA and recognition of this complication was 7 years.[41] Thoracic aortic aneurysm is 17 times more likely to develop in patients with GCA than in people without this disease. To place this risk in context, thoracic aortic aneurysms are twice as likely to complicate GCA as lung cancer is to result from smoking. Abdominal aortic aneurysm is also 2.4 times more common in patients with GCA.[3,41] In aggregate, nearly one out of five patients (18%) with GCA develops an aortic aneurysm or dissection.[58] Patients with large artery disease often do not have headache or other classic manifestations of GCA, and less than 50% have an abnormal temporal artery biopsy. Computed tomography (CT) angiography and magnetic resonance angiography (MRA) are the imaging modalities most commonly used to detect large artery disease in GCA.

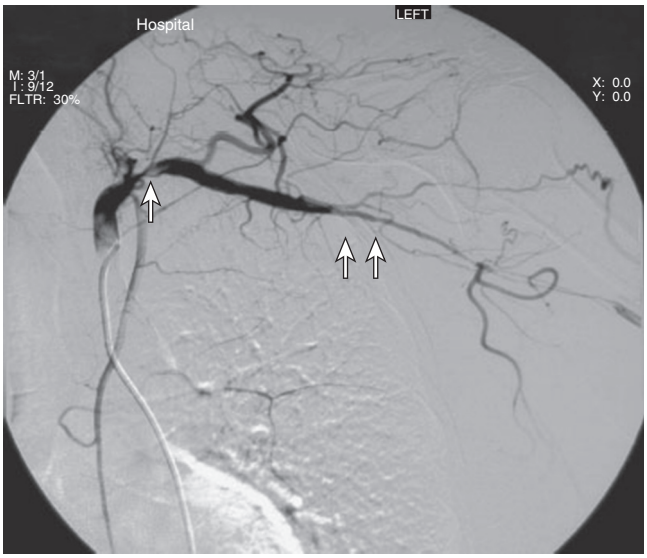

**Figure 88-6** CT angiogram showing giant cell arteritis causing abrupt narrowing of segments of the left subclavian *(arrowhead)* and axillary *(double arrowheads)* arteries. *(Courtesy Dr. Elliot Levy.)*

In women, GCA can uncommonly present as a breast or ovarian mass.[53,60] The mass lesions in these tissues result from granulomatous inflammation in and around the arteries. Angina pectoris, congestive heart failure, and myocardial infarction secondary to coronary arteritis occur rarely.

**Clinical Subsets.** Studies suggest that GCA is not just one disease but, rather, a number of clinical subsets that are explained by the differential expression of inflammatory cytokines.[61] Ischemic events including blindness, stroke, and large artery disease occur more commonly in patients who express high levels of IFN-γ and low levels of IL-6.[61] In contrast, patients who produce high amounts of IL-6 are more likely to have strong inflammatory features (such as fever and constitutional symptoms) and are less likely to develop vision loss or other ischemic events.[61-63]

## Polymyalgia Rheumatica

As in GCA, PMR patients are characteristically in good health before the onset of disease.[11] Systemic manifestations such as malaise, low-grade fever, and weight loss are present in more than half of the patients, and may be the initial symptoms of disease. High, spiking fevers are uncommon in PMR in the absence of GCA.[38] Arthralgias and myalgias may develop abruptly or evolve insidiously during weeks or

months.[2] Malaise, fatigue, and depression, along with aching and stiffness, may be present for months before the diagnosis is made. In most patients, the shoulder girdle is the first to become symptomatic; in the remainder, the hip or neck is involved at the onset. The discomfort may begin in one shoulder or hip, but usually becomes bilateral within weeks. Symptoms center on the proximal limb, axial musculature, and tendinous attachments. Morning stiffness resembling that of RA and "gelling" after inactivity are usually prominent. If the symptoms are severe, aching is more persistent. Although movement of the joints accentuates the pain, it is often felt in the proximal extremities rather than in the joints.[2] Distal joint pain and swelling occur in some cases, including diffuse distal extremity swelling with pitting edema.[64] Pain at night is common, and movement during sleep may awaken the patient. Muscle strength is generally unimpaired, although pain with movement makes the interpretation of strength-testing maneuvers difficult. Pain with movement also makes it difficult for patients to get out of bed or the bathtub. In the later stages of the syndrome, muscle atrophy may develop, and contracture of the shoulder capsule may result in limitation of passive and active motion.

As noted, the presence of bursal inflammation and synovitis in PMR has been described by many authors and is undoubtedly the cause of many of the findings in this condition.[6] A careful examination may reveal transient synovitis of the knees, wrists, and sternoclavicular joints. The shoulders and hips are covered by heavy muscles, and minimal effusions of slight synovitis are not palpable on physical examination. Synovitis has been documented by biopsies, synovial analysis, joint scintiscans, ultrasonography, and MRI.[38-40]

## Laboratory Studies

Except for the findings on arterial biopsy, laboratory results in PMR and GCA are similar (Table 88-5). A mild to moderate normochromic anemia is usually present in both diseases during their active phases. Leukocyte and differential counts are generally normal. A markedly elevated ESR and C-reactive protein (CRP) level are characteristic of both.[65,66]

**TABLE 88-5** Physical Findings and Laboratory Abnormalities in Giant Cell Arteritis

| Feature | Frequency (%) |
|---|---|
| Any temporal artery abnormality | 65 |
| Prominent or enlarged temporal artery | 47 |
| Absent temporal artery pulse | 45 |
| Scalp tenderness | 31 |
| Any funduscopic abnormality | 31 |
| Abnormal ESR | 96 |
| ESR >50 mm/hr | 83 |
| ESR >100 mm/hr | 39 |
| Anemia | 44 |

ESR, Erythrocyte sedimentation rate.

Modified from Smetana GW, Shmerling RH: Does this patient have temporal arteritis? *JAMA* 287:92, 2002.

In a study of 177 patients who had biopsy-proven GCA and measurement of both CRP and ESR, the CRP was minimally more sensitive than the ESR (86.4% vs. 84.2%).[66] The odds ratio of concordantly elevated CRP and ESR was 3.06.[66] Seven untreated patients (4%) had normal values for both ESR and CRP. The patients with normal inflammatory markers were more likely to have PMR and less likely to have constitutional symptoms or anemia.[66] An ESR higher than 100 mm/hr (Westergren method) is common, but untreated biopsy-proven cases of GCA may be associated with normal or nearly normal levels.[65,66] Of the GCA patients, 10.8% presented with an ESR of less than 50 mm/hr, and 3.6% had a rate of less than 30 mm/hr.[65] Rare individuals appear to be unable to develop an elevated ESR or CRP during any inflammatory process, including active GCA. The ESR and CRP is also liable to be relatively low or normal in patients who have been receiving corticosteroids for another condition.[65] Thus a normal ESR or CRP does not exclude the presence of GCA, especially in a patient with otherwise classic symptoms and findings. Platelet counts are often increased.

Nonspecific changes in plasma proteins are often present and include a decrease in the concentration of albumin and an increase in $\alpha_2$-globulins, fibrinogen, and other acute-phase reactant proteins. Slight increases in $\gamma$-globulins and complement may be present. Results of tests for anti-nuclear antibodies and rheumatoid factor are generally negative.

Liver function test results are mildly abnormal in approximately one-third of patients with GCA and in a slightly smaller number of those with PMR. An increased alkaline phosphatase level is the most common abnormality, but increases in aspartate transaminase and prolonged prothrombin time may also be found. Liver biopsy specimens are generally normal; granulomatous hepatitis has been observed.[38] Renal function and urinalysis are usually normal. Red blood cell casts are found in some instances, but their presence does not correlate with clinical large artery involvement.[25]

Levels of serum creatine kinase and other enzymes reflecting muscle damage are normal. Electromyograms are usually normal, and muscle biopsy shows normal histologic features or only the mild atrophy characteristic of disuse.

Synovial fluid analyses reported in GCA or PMR show evidence of mild inflammation including increased synovial fluid leukocyte counts, with a mean of 2900 cells/mm$^3$ but a range from 300 to 20,000 cells/mm$^3$; 40% to 50% are polymorphonuclear leukocytes. Synovial fluid complement levels are usually normal. In some instances, synovial biopsy has shown lymphocytic synovitis.[39,40]

Serum IL-6 levels are elevated in patients with PMR and GCA and appear to closely parallel the inflammatory activity.[67] Levels of factor VIII or von Willebrand factor are elevated in patients with GCA and PMR.

## Differential Diagnosis

Evidence that PMR and GCA are related and should be considered different manifestations of a common disease process is abundant.[11,24] The associations with age, ethnicity, geographic region, and class II HLA alleles are the same in both disorders. Moreover, both disorders involve overproduction of many of the same inflammatory cytokines.

Between 30% and 50% of patients with GCA develop PMR. Approximately 10% to 15% of patients who appear to have only PMR have positive temporal artery biopsies. In the absence of symptoms of GCA (e.g., headache, jaw claudication, visual symptoms, high fever), PMR by itself does not appear to cause vision loss and responds to low doses of glucocorticoids.[11]

The diagnosis of GCA should be considered in any patient older than 50 years who experiences loss of vision, diplopia, new form of headache, jaw claudication, PMR, FUO, unexplained constitutional symptoms, anemia, and a high ESR. GCA can cause so many forms of cranial discomfort (e.g., headache, scalp tenderness, jaw claudication, pain of the throat, gums, and tongue) that the disease should also be considered in any patient older than 50 years in whom new, unexplained "above-the-neck" pain develops. The protean manifestations of GCA mean that it should also be considered in the differential diagnosis of an older patient seen with dry cough, stroke, arm claudication, or acute C5 radiculopathy accompanied by other classic symptoms or findings of GCA.

Only a few individual symptoms or findings substantially increase or decrease the likelihood that a patient has this disease[46] (Table 88-6). For example, jaw claudication, diplopia, abnormal temporal artery signs, scalp tenderness, and ESR greater than 50 mm/hr increase the likelihood that a patient has GCA.[46] In one series of 373 patients, the presence of either jaw claudication or diplopia increased the likelihood of a positive biopsy by more than threefold; the presence of both jaw claudication and double vision had a 100% positive predictive value for a diagnostic temporal artery biopsy.[68] Conversely, the absence of headache or temporal artery abnormalities on physical examination, the presence of synovitis, and a normal ESR reduce the likelihood of GCA.

A large number of disorders can mimic GCA (Table 88-7). There are many causes of monocular vision loss besides vasculitis, including arteriosclerosis-induced thromboembolic disease.[47] Patients with nonarteritic vision loss do not have other GCA-related symptoms, signs, or findings. The funduscopic examination may help by revealing Hollenhorst plaques in cases caused by cholesterol emboli. Anterior ischemic optic neuropathy, the most common cause of vision loss in GCA, can also be caused by arteriosclerosis. Nonarteritic optic neuropathy invariably produces a small optic disc and cup-to-disc ratio, whereas GCA-related optic neuropathy results in an optic disc of variable size.[47] Thus a normal size or large cup in a patient with anterior ischemic optic neuropathy suggests GCA until proven otherwise.[47]

Constitutional symptoms with anemia and an elevated ESR in an older person may also be produced by occult infections (e.g., tuberculosis, bacterial endocarditis, HIV) or malignancy (especially lymphoma and multiple myeloma). These diagnoses highlight the value of selective serologic tests, imaging studies, and immunoelectrophoresis in appropriate patients. Systemic amyloidosis can closely mimic GCA, which is one of the few disorders other than GCA that causes jaw claudication. The amyloid deposits in the temporal artery may not be detected unless the specimen is stained with Congo red. Polyarthritis in an older patient is much more likely to be caused by RA than by GCA. In one study of 520 GCA patients, fewer than 2% developed polyarthritis before GCA was diagnosed.

**TABLE 88-6** Likelihood Ratios* for Symptoms, Signs, and Laboratory Findings in Giant Cell Arteritis

Modified from Smetana GW, Shmerling RH: Does this patient have temporal arteritis? *JAMA* 287:92, 2002.

Criteria for the classification of GCA have been formulated and can help differentiate this arteritis from other forms of vasculitis[69] (see Table 88-1). TA, similar to GCA, can affect the aorta and the major arterial branches to the head and arms. TA, however, is a disease of young women. Anti-neutrophil cytoplasmic antibody (ANCA)–associated granulomatous vasculitis (AGV) can affect the temporal artery and, along with systemic amyloidosis, is an exception to the rule that jaw claudication is pathognomonic for GCA. AGV, however, almost always produces telltale involvement of the respiratory tract or kidneys and is associated with ANCAs. Polyarteritis nodosa can also affect the temporal artery and should be considered if the biopsy does not contain giant cells and the patient has other features atypical for GCA such as mesenteric arteritis. Fibrinoid necrosis of the vasa vasorum occurs in polyarteritis but

| Endocrine disorders | Hypothyroidism |
| Remitting, seronegative synovitis with pitting edema | — |

rarely, if ever, in GCA. Primary angiitis of the central nervous system differs from GCA in that it affects the intracranial arteries.

The diagnosis of PMR is clinical and depends on eliciting the symptoms and findings noted earlier. Two sets of criteria for the diagnosis have been proposed[2,3] (see Table 88-2). Several disorders can mimic PMR (see Table 88-7). Distinguishing early RA from PMR can be difficult, especially in the 15% of patients who are rheumatoid factor-negative, and in those few patients with RA who have not yet developed prominent synovitis of the small joints of the hands and feet. Patients with polymyositis complain much more of weakness than of pain—the opposite symptom pattern reported by patients with PMR. In addition, in polymyositis, levels of muscle enzymes are elevated and electromyograms are abnormal. Although patients with neoplasms may have generalized musculoskeletal aching, no association exists between PMR and malignant neoplasia. Therefore, a search for an underlying tumor is not necessary unless some clinical evidence for a tumor is present or the patient has an atypically poor response to low-dose prednisone.

Some patients with chronic infections such as bacterial endocarditis may have findings that simulate PMR, and blood cultures should be obtained in patients with fever. Patients with fibromyalgia usually do not have typical morning stiffness and have laboratory test results that are normal or nearly so. Rarely, the stiffness of early Parkinson's disease can be confused with PMR if the bradykinesia and tremor of Parkinson's disease are subtle or absent. Lumbar spinal stenosis sometimes causes patients to complain of pain and stiffness in the hip girdle area. The absence of symptoms above the waist helps differentiate it from PMR. Cholesterol-lowering statin drugs can produce myalgia with or without muscle enzyme elevations but rarely mimic PMR. Hypothyroidism in the elderly can mimic many conditions, including PMR. A peculiar syndrome of remitting, seronegative synovitis with pitting edema (designated *$RS_3PE$ syndrome*) may be difficult to differentiate from PMR, and they may be related disorders. Acute symmetric polysynovitis of distal joints with pitting edema of the hands and feet develops in patients with the $RS_3PE$ syndrome. $RS_3PE$ syndrome and PMR both respond to NSAIDs and low-dose prednisone.[11,69]

## Diagnostic Evaluation in Giant Cell Arteritis

Temporal artery biopsy is the "gold standard" for diagnosing GCA.[11,70] Because GCA does not involve the artery in a continuous fashion, temporal artery biopsy should be directed to the symptomatic side, if evident. Removing a small (1 to 2 cm) section of temporal artery is usually adequate in patients who have palpable abnormalities of the vessel.[71] Otherwise, the surgeon should try to excise a 4 to 6 cm sample, and the pathologist should examine multiple sections.[11] In skilled hands, temporal artery biopsy is virtually free of morbidity or mortality. Scalp necrosis can rarely complicate active GCA but has not developed as a consequence of temporal artery biopsy.[70]

Temporal artery biopsies performed at institutions experienced in treating GCA are sensitive and have a high negative predictive value. At the Mayo Clinic, the sensitivity of temporal artery biopsy is approximately 90% to 95%, meaning that only 5% to 10% of patients with negative biopsies will subsequently be proved (by additional biopsy, angiography, or autopsy) to have GCA and require corticosteroid therapy.[70] The sensitivity figures noted previously include some patients who underwent bilateral temporal artery biopsy. Estimates of the value of bilateral biopsies vary.[69,72,73] Of 234 cases of biopsy-proven GCA, unilateral biopsy was positive in 86% and the second biopsy was positive in 14%.[69] Other studies indicate that a second temporal artery biopsy improves the diagnostic yield by only 3% to 5%.[73]

Management of a patient with a negative unilateral biopsy depends on how strongly the patient's clinical picture suggests GCA (Figure 88-7). When GCA is still strongly suspected, a second biopsy or an imaging test (see susequent discussion) should be considered. Opting for a second temporal artery biopsy probably makes most sense in patients who have jaw claudication or diplopia. Patients whose main symptom is occipital headache may be best diagnosed by biopsy of the occipital artery.[74] Patients who have signs of subclavian and axillary disease manifested by arm claudication, unequal arm blood pressures, and supraclavicular or axillary bruits may be diagnosed by angiogram, MRA, or CT scan.[61] Typically, patients with extracranial GCA have smooth, tapered stenosis or occlusion of the subclavian, axillary, and proximal brachial arteries. In one series, temporal artery biopsy was positive in only 58% of patients with larger artery involvement.[61] MRI and CT are the best-established methods for detecting aortic involvement by GCA.[11]

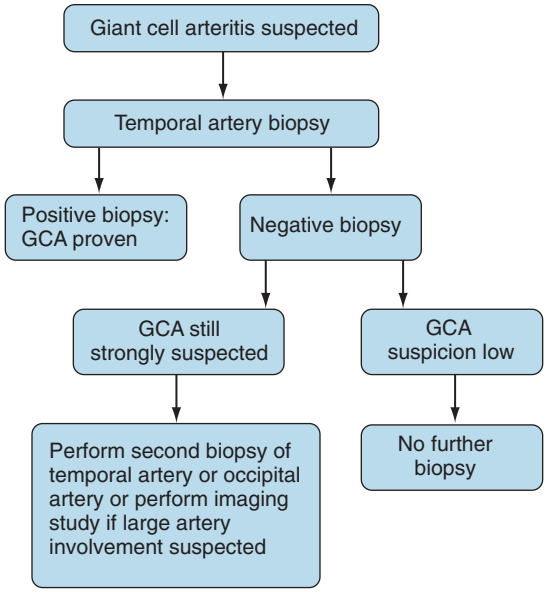

**Figure 88-7** Algorithm for diagnosing giant cell arteritis (GCA).

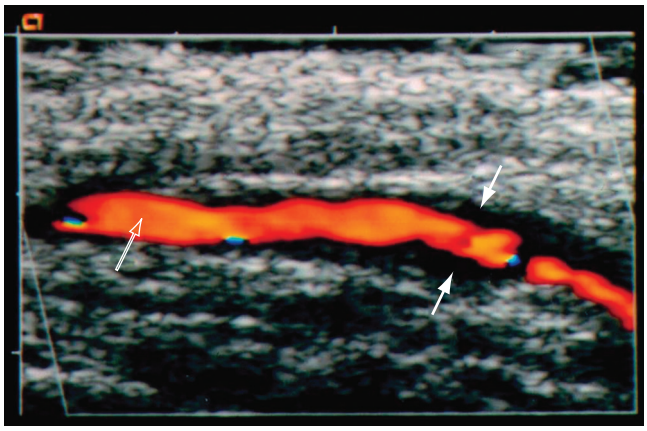

**Figure 88-8** Color duplex ultrasound examination of a swollen, tender temporal artery in a patient with giant cell arteritis. The variably thickened artery wall is visible as a clear "halo" *(solid arrows)* around the lumen in the center *(open arrow)*. *(Courtesy Dr. Gene Hunder.)*

Other imaging techniques have been proposed to assist in the diagnosis of GCA. Color duplex ultrasonography showed abnormalities of the temporal artery in 28 of 30 patients with GCA (sensitivity of 93%).[75] The most characteristic finding was a dark halo around the lumen of the temporal artery (Figure 88-8). However, the diagnostic value of ultrasonography is limited by the absence of expertise with this technique at most medical centers and conflicting estimates of its sensitivity and specificity.[76-78] One meta-analysis of 2036 patients in 23 studies estimated that the sensitivity and specificity of the halo sign were 69% and 82%, respectively. Another study found that ultrasonography did not improve the diagnostic accuracy of a carefully performed physical examination.[79] High-resolution MRI can demonstrate contrast enhancement and mural thickening of superficial cranial arteries in GCA. Small studies have found a sensitivity of 91% and a specificity of 73%, compared with temporal artery biopsy.[76-78] Best results are achieved with 3-T MRI scanners.[78] PET has shown promise in detecting occult involvement of the aorta and great vessels by GCA; however, estimates of sensitivity have varied from 65% to 100% and specificity from 77% to 99%.[76,78] PET scanning cannot image small arteries that are near highly metabolic tissues such as the brain, and thus cannot be used to study superficial extracranial arteries. Repeated PET scans do not predict the risk of relapse.[78] For the rare patient who has a compelling story for GCA but negative bilateral temporal artery biopsies, one should reconsider conditions that mimic GCA described earlier (e.g., ask the pathologist to stain the biopsied arteries with Congo red to rule out systemic amyloidosis). If no other diagnosis becomes evident, then it is reasonable to search for occult large vessel disease with an imaging test such as a PET scan or MRA to look for occult aortic disease. Rarely a patient's clinical picture strongly indicates GCA despite negative biopsies and imaging. In this case, the physician can treat the patient for GCA while watching vigilantly for the emergence of another disease.

## Treatment and Outcome

Most authorities recommend starting glucocorticoid therapy as soon as the diagnosis of GCA is strongly suspected. The main goal of treatment is to prevent loss of vision. Because vision loss is almost always permanent, it seems prudent to initiate corticosteroid therapy as early as possible, even before the biopsy is performed. Fortunately, the diagnostic yield of temporal artery biopsy is not altered by corticosteroid therapy for at least 2 weeks, and perhaps longer.[80]

### Initial Treatment for Giant Cell Arteritis

An initial dose of prednisone 40 to 60 mg/day or equivalent is adequate in nearly all cases.[11] Dividing the dose for the first 1 to 2 weeks may accelerate the rate of improvement. If the patient does not respond promptly, the dose should be increased. One double-blind, placebo-controlled, randomized trial involving 27 patients with GCA suggested that initiating treatment with intravenous methylprednisolone (15 mg/kg of ideal weight per day) for 3 days allowed more rapid tapering of oral corticosteroids and increased the likelihood of achieving a sustained remission.[81] The small size of that study and the possible overreliance on laboratory tests to define relapse raise questions about the generalizability of these results. Indeed, a randomized, multicenter, controlled trial of intravenous pulses of a single dose of 240 mg of methylprednisolone in the initial treatment of 164 GCA patients showed no benefit.[82] High-dose, intravenous-pulse methylprednisolone (1000 mg/day) for 3 days has also been tried in patients with recent loss of vision. Unfortunately, the loss remains permanent in the vast majority of patients. The occlusive nature of the vasculitis argues against any role of acute thrombolytic therapy in the treatment of blindness.

Because all patients with GCA require months of glucocorticoid therapy, measures to prevent osteoporosis should be started early, as described in Chapter 101. In addition, because traditional risk factors for atherosclerosis (e.g., smoking, hypertension, diabetes, hypercholesterolemia) might increase the risk of vision loss or stroke in GCA,[49]

reducing or eliminating these risk factors is an important part of overall management.

### Subsequent Treatment for Giant Cell Arteritis

The initial effective dose of prednisone should be continued until all reversible symptoms, signs, and laboratory abnormalities have reverted to normal.[11] This usually takes 2 to 4 weeks. After that, the dose can be gradually reduced by a maximum of 10% of the total dose each week or every 2 weeks.[11] The decision to reduce prednisone should be based on a composite assessment of the patient's symptoms, signs, and laboratory markers of inflammation. The ESR and serum concentration of CRP are generally the most convenient and helpful laboratory markers of inflammation. The ESR is reliable only if performed promptly after the blood sample is obtained. Serum levels of IL-6 appear to be the most sensitive marker of activity of GCA, but this test is not widely available.[83] CRP may be slightly more sensitive than ESR in detecting flares.[83] At some point during drug tapering, the ESR or CRP may rise above normal again, and further reductions of prednisone should be temporarily interrupted. If, over the next week or so, the patient does not develop signs or symptoms of active GCA, reductions in prednisone (at smaller decrements and at longer intervals) can usually be resumed. Doses of 10 to 20 mg/day or more are often required for several months before further reductions are possible. However, if the prednisone dose is dependent on the levels of inflammatory markers with no regard to the patient's overall clinical context, there is a risk of corticosteroid-related side effects. Gradual reductions allow the identification of the minimal suppressive dose and help avoid exacerbations that result from too-rapid tapering. Even with a gradual reduction of prednisone, more than 50% of patients experience flares of disease activity during the first year.[84] These exacerbations can usually be handled by increasing the prednisone by 10 mg above the last dose at which the disease was controlled.

Most patients with GCA have a chronic disease that requires prednisone treatment for at least 1 year and often for several years; a minority of patients run a self-limited course of only several months.[11] Glucocorticoids can eventually be reduced and discontinued in some patients. Many patients require low doses of prednisone for several years or more to control musculoskeletal symptoms.

The nearly universal experience of serious side effects associated with daily corticosteroids has prompted the search for alternative steroid-sparing treatments. Unfortunately, to date, none has been convincingly effective. Alternate-day prednisone, for example, is not effective initial therapy for GCA. Similarly, cytotoxic drugs, dapsone, anti-malarials, and cyclosporine have not been clearly shown to be effective.[11,85] The combination of weekly low-dose oral methotrexate and prednisone was steroid sparing in one placebo-controlled, double-blind treatment trial but not in another.[84] Statins do not appear to modify the course of GCA or the need for corticosteroids.[86]

Delineation of the cells and cytokines involved in the pathogenesis of GCA has invited trials of biologic agents. For example, the putative role of TNF in propagating a granulomatous vasculitic process suggested that TNF inhibitors might be effective in treating GCA. Unfortunately, neither infliximab nor etanercept is effective in GCA.[87,88] High expression of IL-6 in affected arteries and in the circulation of patients with GCA has opened the door for trying to treat with tocilizumab, a humanized monoclonal anti-IL-6 receptor antibody.[89-91] In the approximately 2 dozen patients with GCA reported in case reports and small series to have received tocilizumab, the drug appeared to be effective in reducing symptoms. Enthusiasm for this therapy must be tempered until the availability of data from large, randomized-controlled trials. In addition, most patients relapsed after the drug was stopped. The possibility that IL-6 inhibitors may suppress the systemic symptoms and signs without eliminating the vasculitis has been suggested by an autopsy in the one patient treated with tocilizumab who had appeared to respond and died of other causes, which showed persistent active arteritis.[90] A few case reports have described apparent responses in GCA patients treated with the anti-CD20 monoclonal antibody rituximab to deplete B cells or with anakinra to inhibit IL-1 receptors.[92]

No prospective, double-blind trials have tested the potential adjunctive role of aspirin or anti-coagulants in the treatment of GCA.[93] However, aspirin is theoretically appealing because, in experimental models of GCA, it inhibits IFN-γ production more effectively than prednisone.[94] In addition, three retrospective studies found that patients with GCA taking low-dose aspirin or anti-coagulant therapy had a threefold to fivefold lower risk of an ischemic event such as vision loss.[95-97] Together, these studies suggest that it is reasonable to administer low-dose aspirin to patients with GCA who do not have an excessive risk of gastrointestinal bleeding.

Arm claudication from GCA affecting the subclavian and axillary arteries usually improves or resolves with corticosteroid therapy. Rare patients with GCA who have severe upper extremity claudication unresponsive to corticosteroid therapy may benefit from balloon angioplasty. In one series of 10 patients, all improved initially after angioplasty, but symptomatic restenosis developed in 50% during 2 months.[98] In all cases, recurrent stenosis developed in vascular lesions that were greater than 3 cm long.[98]

Thoracic aortic aneurysm is greatly increased in patients with GCA. Although it can be present at the outset, aneurysms are usually noted late in the disease course, an average of 7 years after onset. Some authorities have recommended annual chest radiographs to detect thoracic aortic aneurysms.

### Treatment for Polymyalgia Rheumatica

Patients with PMR without symptoms or signs or biopsy evidence of GCA are usually treated initially with prednisone 10 to 20 mg/day or equivalent.[99,100] A systematic review of 30 studies recommended starting treatment with prednisone at 15 mg/day; lower initial doses were less effective and higher doses were more toxic.[101] Salicylates and NSAIDs have been used but are less appealing; salicylates and NSAIDs adequately control symptoms in only a minority of patients with milder symptoms and add to overall adverse drug reactions when they are used with glucocorticoids.[2,8] Prednisone therapy usually results in rapid (often overnight) and dramatic improvement of the musculoskeletal aching

and stiffness and a more gradual return of the ESR and CRP level to normal. A minority of patients with isolated PMR fail to respond to prednisone 20 mg/day after 1 week and may require as much as 30 mg/day as initial treatment. Studies suggest that these resistant cases are more likely to have ESRs greater than 50 mm/hr and high levels of IL-6. If a patient does not respond to prednisone 30 mg/day for 1 week, this should prompt a search for an alternative diagnosis (Figure 88-9). Lower doses of prednisone might not suppress an underlying arteritis if it is present. Thus, the patient must be observed carefully even though the aching improves. In patients with PMR, the dose should be reduced gradually as soon as symptoms permit. Pre-treatment ESR, CRP, and IL-6 concentrations and initial responses to therapy appear to be helpful in dividing patients into subsets with different treatment requirements.[99] If the laboratory test results become normal while the patient is receiving a smaller dose, the likelihood of an underlying active vasculitis seems to be much less, and the risk of vascular complications is smaller. However, this is not true in all instances because active arteritis has been observed even though the ESR improved.

Once the symptoms, signs, and laboratory abnormalities of PMR have resolved (usually after 2 to 3 weeks of therapy), the daily dose of prednisone can be slowly tapered. Some experts recommend tapering prednisone by 2.5 mg every week until 10 mg/day is reached, at which point the decrements should be reduced by 1 mg each month.[101] Flares are common, necessitating a dose increase to achieve remission before attempting a slower taper. The minority of patients with PMR succeed in tapering off prednisone in less than 1 year. Many require at least 2 years of low-dose prednisone.[102]

Some, but not all, studies suggest that oral methotrexate (10 mg once a week for 48 weeks) can reduce the long-term need for corticosteroids in patients with PMR.[101,103] It is not yet known whether the small but statistically significant reduction in prednisone use achieved with methotrexate results in a clinically important reduction in prednisone-related side effects.

## TAKAYASU'S ARTERITIS

TA, also known as *pulseless disease* or *occlusive thromboaortopathy*, is a form of vasculitis of unknown cause that chiefly affects the aorta and its major branches, most frequently in young women.[104,105] The disease is named for the Japanese ophthalmologist who, in 1908, described a young woman with peculiar retinal arteriovenous anastomoses caused by retinal ischemia from large vessel vasculitis.[1]

### American College of Rheumatology Classification Criteria

The ACR classification criteria for the diagnosis of TA are listed in Table 88-8.

### Epidemiology

Although TA has been described worldwide, it occurs most commonly in Japan, China, India, and Southeast Asia. The disease is also prevalent in Mexico. Whereas the incidence of TA in Japan is nearly 150 per million per year, it is only 0.2 to 2.6 per million in Western Europe and North America. TA affects women eight times more frequently than men. The median patient age at onset is 25 years; however,

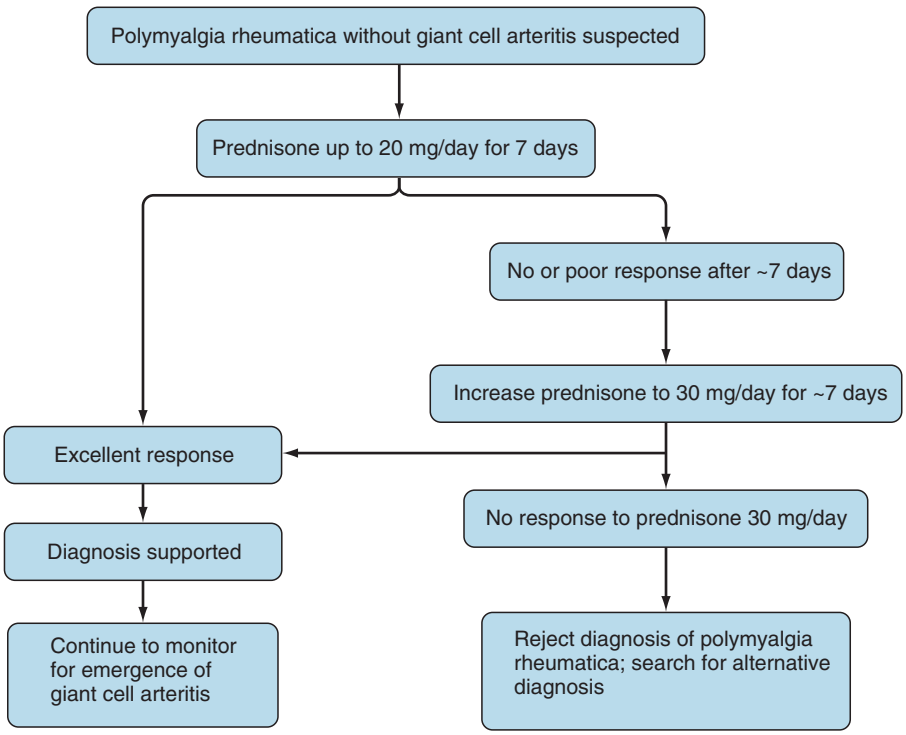

**Figure 88-9** Algorithm for diagnosing polymyalgia rheumatica without giant cell arteritis.

**TABLE 88-8** American College of Rheumatology Classification Criteria for Takayasu's Arteritis*

| |
|---|
| Onset before age 40 yr |
| Limb claudication |
| Decreased brachial artery pulse |
| Unequal arm blood pressure (>10 mm Hg) |
| Subclavian or aortic bruit |
| Angiographic evidence of narrowing or occlusion of aorta or its primary branches, or large limb arteritis |

*The presence of three or more of the six criteria is sensitive (91%) and specific (98%) for the diagnosis of Takayasu's arteritis.

American College of Rheumatology 1990 criteria for the classification of Takayasu arteritis, *Arthritis Rheum* 33:1129, 1990; From Hellmann DB: Takayasu arteritis. In Imboden JB, Hellmann DB, Stone JH, editors: *Current rheumatology diagnosis and treatment,* New York, 2004, Lange Medical Books/McGraw-Hill, p 245.

approximately 25% of cases begin before age 20, and 10% to 20% of patients are seen after age 40 years.[104] Immunogenetic studies in Japanese patients suggest an association with several HLAs, especially HLA-Bw52, Dw12, DR2, and DQw1. Different HLA associations have been found in Koreans and Indians. No HLA association has been found in North American patients. In Mexican patients, TA has been associated with previous exposure to *Mycobacterium tuberculosis*.

## Etiology and Pathogenesis

The cause of TA is unknown. The nearly identical pathology in TA and GCA has invited speculation that the model of immunopathogenesis of GCA described earlier (see Figure 88-3) applies to TA as well.[24,44] Indeed, some have argued that TA and GCA represent a spectrum within the same disease. Similar to GCA, TA is thought to result from an autoimmune process that targets large elastic-containing arteries. Both feature panarteritis involving infiltration of dendritic cells; T cells (including αβ, γδ, and cytotoxic); natural killer cells; and macrophages. In TA, the majority of lymphocytes are perforin-secreting killer lymphocytes such as T cells and natural killer cells. The T cell receptors in TA, as in GCA, are oligoclonal, suggesting that the vasculitis is driven in both diseases by a T cell response to a specific but unknown antigen.[106] Chronic inflammation of the vessel wall leads to aneurysm formation, stenosis, or thrombosis more frequently in TA than in GCA. Dissection occurs in TA, but is rare and less frequent than in syphilitic aortitis.[107] The late phase of TA, similar to that of GCA, is characterized by intima proliferation with superimposed atherosclerosis, medial necrosis with scarring, and adventitial fibrosis. As in GCA, the inflammatory involvement in TA can be continuous or segmental, with skip areas of normal vessel interposed between involved areas.[107] It is possible that the humoral immune system may play some role in the pathogenesis of TA. Most patients with TA possess anti-endothelial cell antibodies that can damage vessels by inducing endothelial inflammatory cytokine production, adhesion molecules, and apoptosis.

The geographic clustering of cases has suggested that genetics and environmental factors participate in the pathogenesis of TA. However, immunogenetic studies (described in previous text) have not identified any other universally shared genetic risk factors. The young age of onset and the female predominance in TA and in systemic lupus erythematosus have invited speculation about the influence of female hormones in promoting an autoimmune disease process. In some countries, the apparent association of TA with high rates of exposure to tuberculosis has suggested an infectious cause. An animal model of TA has been produced in mice by using a herpesvirus that infects the smooth muscle cells of the media. In that model, the media of large elastic arteries serves as an immunoprivileged site that allows the herpesvirus to propagate a chronic inflammatory response in the aorta and its major branches.[108]

**TABLE 88-9** Clinical Features of Takayasu's Arteritis

| Feature | At Presentation (%) | Ever Present (%) |
|---|---|---|
| Vascular | 50 | 100 |
| Bruit | | 80 |
| Claudication (upper extremity) | 30 | 62 |
| Claudication (lower extremity) | 15 | 32 |

Data based on a study of 60 North American patients reported by Kerr GS, Hallahan CW, Giordano A, et al: Takayasu arteritis. *Ann Intern Med* 120:919, 1994; From Hellmann DB: Takayasu arteritis. In Imboden JB, Hellmann DB, Stone JH, editors: *Current rheumatology diagnosis and treatment,* New York, 2004, Lange Medical Books/McGraw-Hill, p 243.

## Clinical Features

Although the presenting manifestations of TA are protean, the vast majority of patients are seen with symptoms and signs of vascular insufficiency (from stenosis, occlusion, or aneurysm), systemic inflammation, or both[79,104] (Table 88-9). In a North American series of 60 patients followed up at the National Institutes of Health, the most common presenting vascular symptoms were claudication (35%), reduced or absent pulse (25%), carotid bruit (20%), hypertension (20%), carotidynia (20%), lightheadedness (20%), and asymmetric arm blood pressures (15%).[104] Stroke, aortic regurgitation, and visual abnormalities were present at onset in less than 10% of patients. The extreme manifestations of

retinal ischemia noted in Takayasu's original patient are rarely seen now.[104] Permanent loss of vision, the major concern in GCA, rarely develops in TA.

Claudication affects the arms at least twice as frequently as the legs. For many young women, arm claudication first reveals itself as arm pain or fatigue experienced while trying to hold a hair dryer. Overall, bruit is the most common sign, eventually found in 80% of patients. Although bruit over the carotid artery is most frequent, it can also be found in the supraclavicular, infraclavicular, axillary, flank, chest, abdominal, and femoral areas. One-third of patients have multiple bruits.[104] Unequal arm blood pressures eventually develop in half of all patients. Headache, which is common in TA, does not correlate with carotid or vertebral disease, which develops in nearly 40% of patients.[104,109]

Constitutional, musculoskeletal, and other symptoms of systemic inflammation are also common presenting complaints.[79,104] About one in five TA patients presents with fever and malaise, which can be accompanied by night sweats and weight loss. A few patients who have minimal or no signs of vascular insufficiency may appear to have FUO for weeks or months before the diagnosis of TA becomes evident. A minority of patients present with myalgia or arthralgia (see Table 88-9). Some patients have striking midthoracic back pain, perhaps as a result of aortic inflammation irritating nociceptive nerve fibers.

Cardiac involvement occurs eventually in nearly one-third of patients (see Table 88-9).[104] Aortic regurgitation develops in 20% of patients as a result of aortic root dilation. Aortic regurgitation is important because it frequently progresses and may lead to left ventricular dilation with secondary mitral regurgitation and congestive heart failure. Aortic valve replacement is often required eventually. Angina can develop as a result of coronary artery disease. TA of the coronary arteries most often produces ostial lesions but can also produce either diffuse vasculitis of the coronary arteries or aneurysms.[110-112] Myocarditis also occurs in TA and causes potentially reversible congestive heart failure. Pericarditis is rare. TA is, along with Behçet's disease, one of the few forms of vasculitis that can affect the large pulmonary arteries. Although TA of the pulmonary arteries is rare (appearing in less than 3% of patients), affected patients can be seen with cough, chest wall pain, dyspnea, or hemoptysis.

Unlike polyarteritis or GPA, TA rarely causes peripheral neuropathies. Cutaneous manifestations develop in less than 10% of patients with TA.[104] Erythema nodosum is most common, but purpura, livedo reticularis, and ulceration may rarely occur. As in GCA, a minority of patients with TA who have active disease have a persistent, dry cough.

## Laboratory Studies

At presentation, the ESR is more frequently elevated (80%) than the CRP (~50%).[79] Mild anemia and hypergammaglobulinemia are common. The white blood cell count is usually normal or slightly elevated. The platelet count is elevated in one-third of patients, and may exceed 500,000/μL in those with active disease. The serum creatinine and urinalysis are usually normal. Any renal abnormalities are usually secondary to hypertension; unlike ANCA-associated vasculitis, TA rarely causes glomerulonephritis.

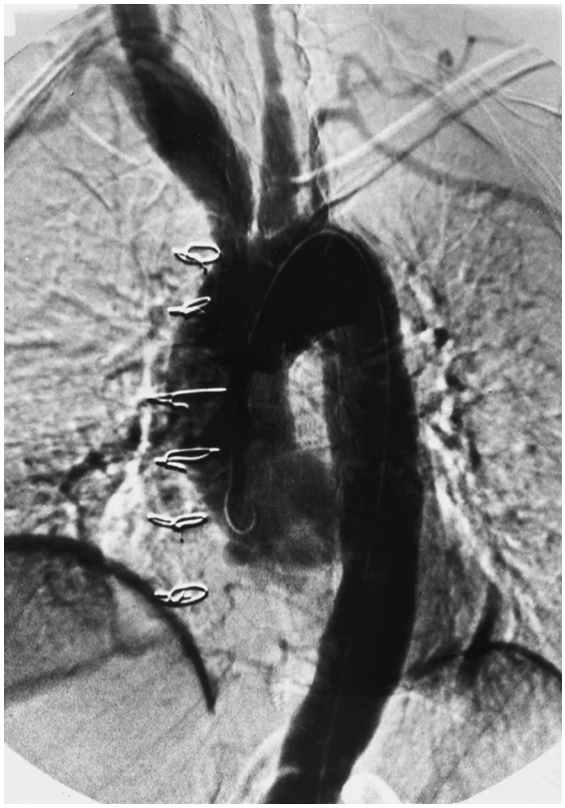

**Figure 88-10** Angiogram showing multiple changes of Takayasu's arteritis including dilation of the aortic root (with surgical wires from previous aortic valve replacement), aneurysmal dilation of the innominate and right carotid arteries, and occlusion of the distal left common carotid artery. *(From Hellmann DB, Flynn JA: Clinical presentation and natural history of Takayasu's arteritis and other inflammatory arteritides. In Perler BA, Becker GJ, editors:* Vascular intervention: a clinical approach, *New York, 1998, Thieme Medical and Scientific Publisher, pp 249–256.)*
